ARSENIC IN THE CENTRAL

OKLAHOMA AQUIFER

Thesis Approved:

Zuhair al-Shaieb

Thesis Advisor

Jim Puckette

Brian J Carter

Timothy J. Gilbertson

Dean of the Graduate College

ACKNOWLEDGEMENTS

The writer expresses his appreciation to Dr. Zuhair Al-Shaieb, thesis advisor, for his guidance, instruction, and assistance in completion of this thesis. Dr. Jim Puckette and Dr. Brian Carter, thesis committee members, for their manuscript evaluations and enlightening discussions. In addition, the writer thanks Dr. Todd Halihan for his instruction and inspiring remarks. Finally, the writer wishes to thank his family; Nina Keester, mother, for her constant encouragement; Wayne Madewell, father-in-law, for his critique of the manuscript; and especially Mariah Madewell, spouse, for her unending support, love, and motivation.

CHAPTER ONE

INTRODUCTION

A concentration of 50 micrograms of arsenic per liter of water will contribute to approximately 1 out of every 100 persons developing some form of cancer during their lifetimes (NRC, 1999). Knowing this health risk, an understanding of arsenic in drinking water is essential. In the Oklahoma City, Oklahoma area one finds a considerable amount of arsenic in ground water of the Central Oklahoma Aquifer. With the elevated concentrations of arsenic one finds in the ground water of the Permian red beds that compose the Central Oklahoma Aquifer and the associated health risk of these elevated concentrations, clearly an understanding of this system becomes imperative.

Objectives

This study will first examine the distribution of arsenic in the Central Oklahoma aquifer; that is, it will identify where one finds arsenic in the aquifer, where levels are highest, and what one finds associated with the arsenic. Second, it will determine the possible source of arsenic in the aquifer. Finally, the study will investigate how the ground water reacts with the solid phase materials to mobilize the arsenic.

Federal Regulation Concerning Inorganic Arsenic in Drinking Water

Human Health Concerns

The Environmental Protection Agency (EPA) imposes drinking water standards for arsenic based on human health risk. The criterion on which to base this regulation is a

carcinogenicity of $10^{-4} - 10^{-6}$ risk or lower (EPA, 1999). While there are three primary modes of exposure, namely, oral, dermal, and inhalation, this study will only address oral and dermal as means to expose the human body to arsenic in ground water.

Dermal Exposure. Dermal exposure to arsenic in drinking water is most likely to occur through bathing. Unfortunately, little information is available concerning human exposure to an aqueous solution containing arsenate or arsenite. However, studies using guinea pigs and mice suggest that direct dermal contact may be of concern at high concentration levels, but lower levels are unlikely to cause significant irritation (Table 1; DHHS, 2000).

Species (Strain)	Exposure/ Duration/ Frequency (Specific Route)	System	NOAEL	LOAEL		Chemical Form
				Less Serious	Serious	
ACUTE EXPOSURE						
Immunological/Lymphoreticular						
Gn pig (Hartley)	Once		580 mg/l			As(+3)
Gn pig (Hartley)	Once		4000 mg/l			As(+5)
INTERMEDIATE EXPOSURE						
Systemic						
Mouse (Rockland)	30 wk 11x/wk	Dermal		6 mg/kg/day; F; (gross hyperplasia, ulceration)		As(+3)

LOAEL = lowest-observable-adverse-effect level; NOAEL = no-observable-adverse-effect level; Gn pig = guinea pig; F = female; wk = week(s); x = time(s)

Table 1. Effect from dermal exposure to designated concentrations of inorganic arsenic (adapted from DHHS, 2000).

Oral Exposure. Oral exposure is a much greater concern when addressing the level of arsenic in drinking water. The two primary forms of arsenic in groundwater are arsenous acid (H_3AsO_3) and arsenic acid (H_3AsO_4) with the trivalent arsenite species more prevalent than the pentavalent arsenate. Once in the human body, arsenite inhibits adenosine triphosphate biosynthesis, which may account for some of it's toxicity (NRC, 1999).

Development of a New Standard

Background. In 1942, the United States government established a drinking water standard of 50 parts per billion (ppb), or 50 micrograms per liter (μg/l), for arsenic. With the adoption of the Safe Drinking Water Act (SDWA) in 1974, the EPA set 50 μg/l as the interim maximum contaminant level (MCL) for total arsenic in drinking water. Amendments to the SDWA in 1986 required the EPA to establish an enforceable MCL for arsenic by 1989; however, due to scientific uncertainty and controversy the EPA did not meet the 1989 goal. Further amendments to the SDWA in 1996 required the EPA to develop a research strategy for arsenic within 180 days of the amendment's enactment; the reviewers of this strategy then asked the EPA to propose a MCL by 2000 and establish a definitive MCL by 2010 or earlier (NRC, 1999).

EPA's 1988 Risk Assessment. Following the 1986 amendments to the SDWA, the EPA published a risk assessment for arsenic in 1988. Using data from a Taiwan study by Tseng et al. (1968) that related elevated cancer rates to elevated arsenic levels in drinking water, the EPA estimated, assuming the average U. S. individual weighs 70 kilograms (kg) and consumes two liters of tap water per day, the lifetime skin cancer risk

associated with a drinking water concentration of 50 μg/l as approximately 2 x 10^{-3} (NRC, 1999). Further analysis indicates that at 50 μg/l the excess lifetime risk of bladder cancer in males may be as high as 1.5 per 1000. Examining the contribution of arsenic to all cancers in both sexes may result in a combined cancer risk approaching 1 in 100 for a drinking water concentration of 50 μg/l (NRC, 1999).

Reducing the Risk. From the 1988 risk assessment and the National Research Council (1999) report, one may recognize that a MCL of 50 μg/l for arsenic exceeds the EPA's goal of 10^{-4} – 10^{-6} risk. On June 22, 2000, the EPA published proposed, health-based, arsenic regulation with a MCL of 5 μg/l (EPA, 2002). However, under pressure from industry, former President Clinton implemented a 10 μg/l MCL just three days before leaving office. Clinton's successor suspended the new rule until February 2002 to allow further research to justify the 10 μg/l standard and the cost associated with compliance.

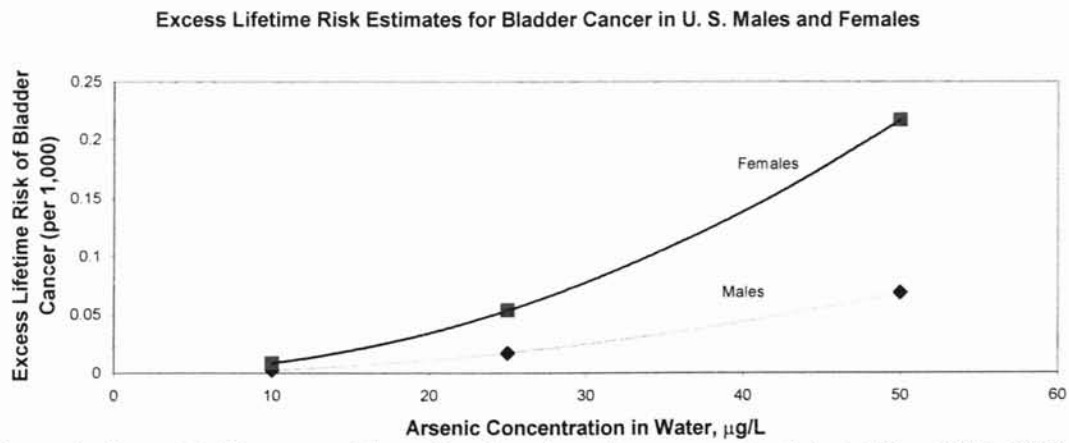

Figure 1. Excess bladder cancer risk as a function of arsenic concentration (adapted from NRC, 1999).

Finally, in March 2002, the EPA published a draft presenting the necessity to adopt a MCL of 10 μg/l for arsenic. The NRC (1999) study indicates that this reduction

could dramatically reduce the lifetime risk of bladder cancer in both males and females (Figure 1). A problem with the NRC study is that it does not adjust for food and cooking water consumption and only examines bladder cancer risk; however, the EPA (2002) report presents findings accounting for food and cooking water Table 2). In addition, the EPA report illustrates how a reduction of the arsenic MCL will reduce mortality and morbidity bladder and lung cancer cases (Table 3).

MCL (μg/l)	Mean Exposed Population Risk	90th Percentile Exposed Population Risk
3	.11 - 1.25 x 10^{-4}	.22 - 2.42 x 10^{-4}
5	.27 - 2.02 x 10^{-4}	.55 - 3.9 x 10^{-4}
10	.63 - 2.99 x 10^{-4}	1.32 - 6.09 x 10^{-4}
20	1.1 - 3.85 x 10^{-4}	2.47 - 8.37 x 10^{-4}

Table 2. Cancer risks for U. S. populations at various proposed MCLs. Lower bound adjusted for food and cooking water, upper bound not adjusted for food and cooking water (adapted from EPA, 2002).

Arsenic Level (μg/l)	Reduced Mortality Cases	Reduced Morbidity Cases	Total Cancer Cases Avoided
3	32.6 - 74.1	24.6 - 64.2	57.2 - 138.3
5	29.1 - 53.7	22.0 - 46.5	51.1 - 100.2
10	21.3 - 29.8	16.1 - 25.9	37.4 - 55.7
20	10.2 - 11.3	8.5 - 8.8	19.0 -19.8

Table 3. Annual bladder and lung cancer cases avoided from reducing arsenic in public drinking water. Mortality based on U. S. rates of 25% for bladder cancer and 88% for lung cancer (from EPA, 2002).

Previous Investigations

The U. S. Geological Survey published five reports over the Central Oklahoma Aquifer as part of the National Water-Quality Assessment. These reports touched on several aspects of the aquifer, such as: diagenesis, geochemistry, hydrologic properties, and aqueous geochemistry. However, when discussing arsenic, the study failed to account for a reduction in the MCL despite indications of an impending reduction.

Method of Investigation

This study required the collection of a vast amount of water quality data. Collection began at the United States Geological Survey database for hydrologic information, namely, the National Water Information System. This data is available for download as text files, which one may easily convert to a Microsoft Excel format. Next, a search of the Environmental Protection Agency database revealed water quality data available as a Microsoft Excel Pivot Table. Merging these two databases provided several hundred water analyses.

Importing the data into EnviroData, a program designed for relational management of site environmental data (Rich, 2000), eased storage, tracking, sorting, and analysis. Using the database one may easily compile needed data, create reports, and export necessary information for use in other applications. Using EnviroData, the writer sorted and exported the analyses into multiple Excel workbooks. Once in Excel format, the author performed necessary calculations and comparisons.

CHAPTER TWO

DESCRIPTION OF THE STUDY UNIT

Areal Extent

The Central Oklahoma Aquifer underlies approximately 8,000 square kilometers of central Oklahoma including all or parts of Cleveland, Lincoln, Logan, Oklahoma, Payne, and Pottawatomie counties (Figure 2). Parkhurst, Christenson, and Schlottmann (1989) define the hydrologic boundaries of the aquifer as the Cimarron and Canadian rivers to the north and south respectively, the Hennessey Group, which acts as the upper confining unit, and the Vanoss Formation, which acts as the lower confining unit (Figure 3).

Geology

Stratigraphy

Five units define the Central Oklahoma Aquifer: (1) the Hennessey Group, (2) the Garber Sandstone, (3) the Wellington Formation, (4) the Chase, Council Grove, and Admire Groups (undivided), and (5) the Vanoss Formation. Reddish-brown shale, mudstone, and very-fine grained sandstone compose the overlying Hennessey Group. Below the Hennessey Group, lenticular beds of fine-grained sandstone, with interbedded siltstone, mudstone, and conglomerate, form the lithologically similar Garber Sandstone and Wellington Formation, which range from approximately 355 to 490 meters thick (Christenson, Morton, and Mesander, 1992). Next, the Chase, Council Grove, and

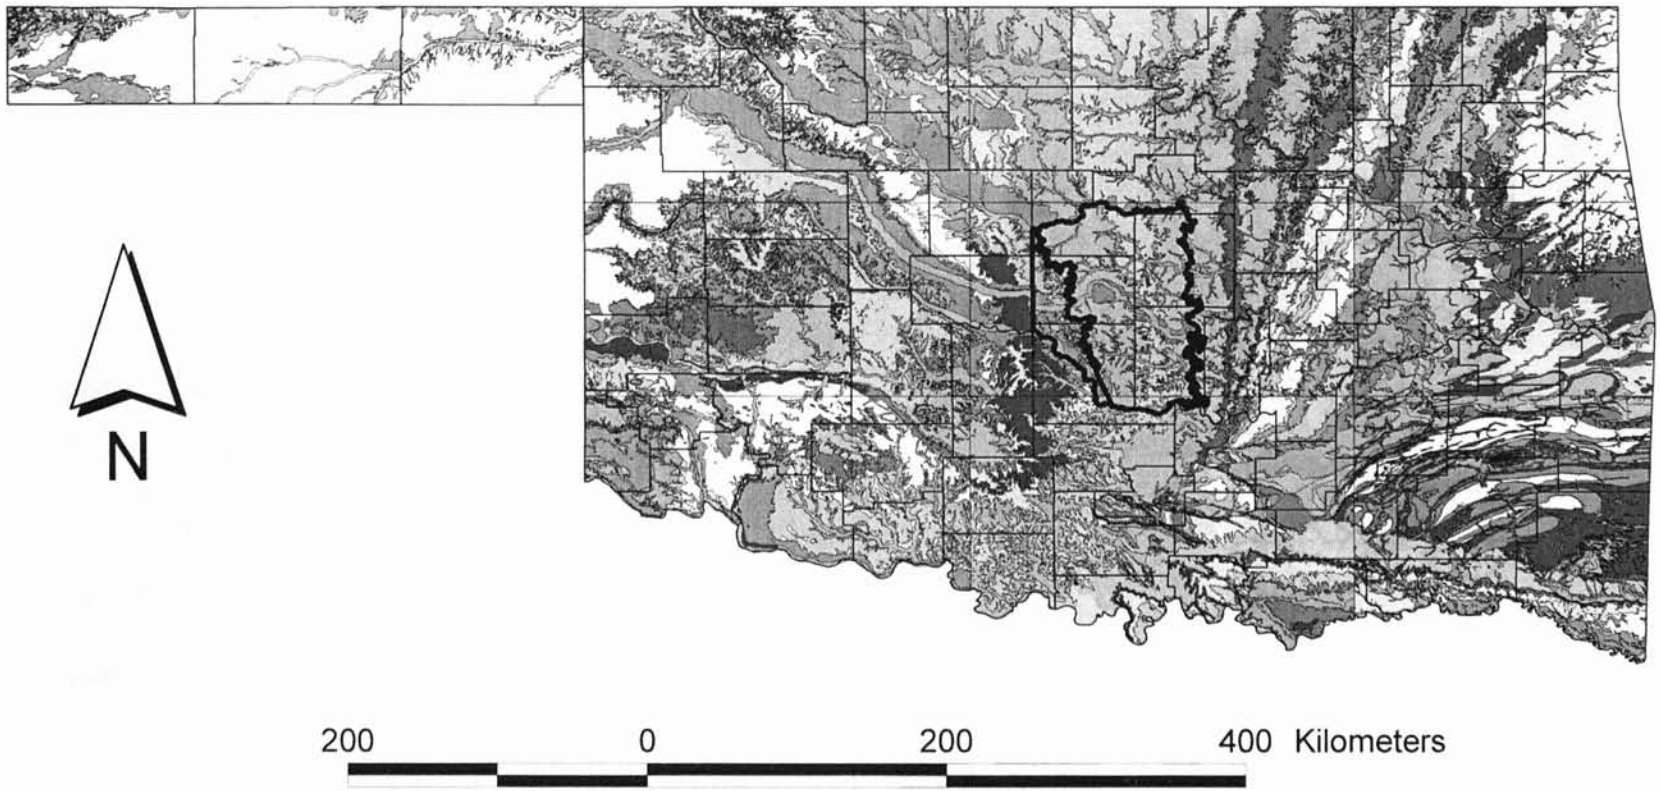

Figure 2. Map of Oklahoma, Counties, and Central Oklahoma Aquifer boundaries.

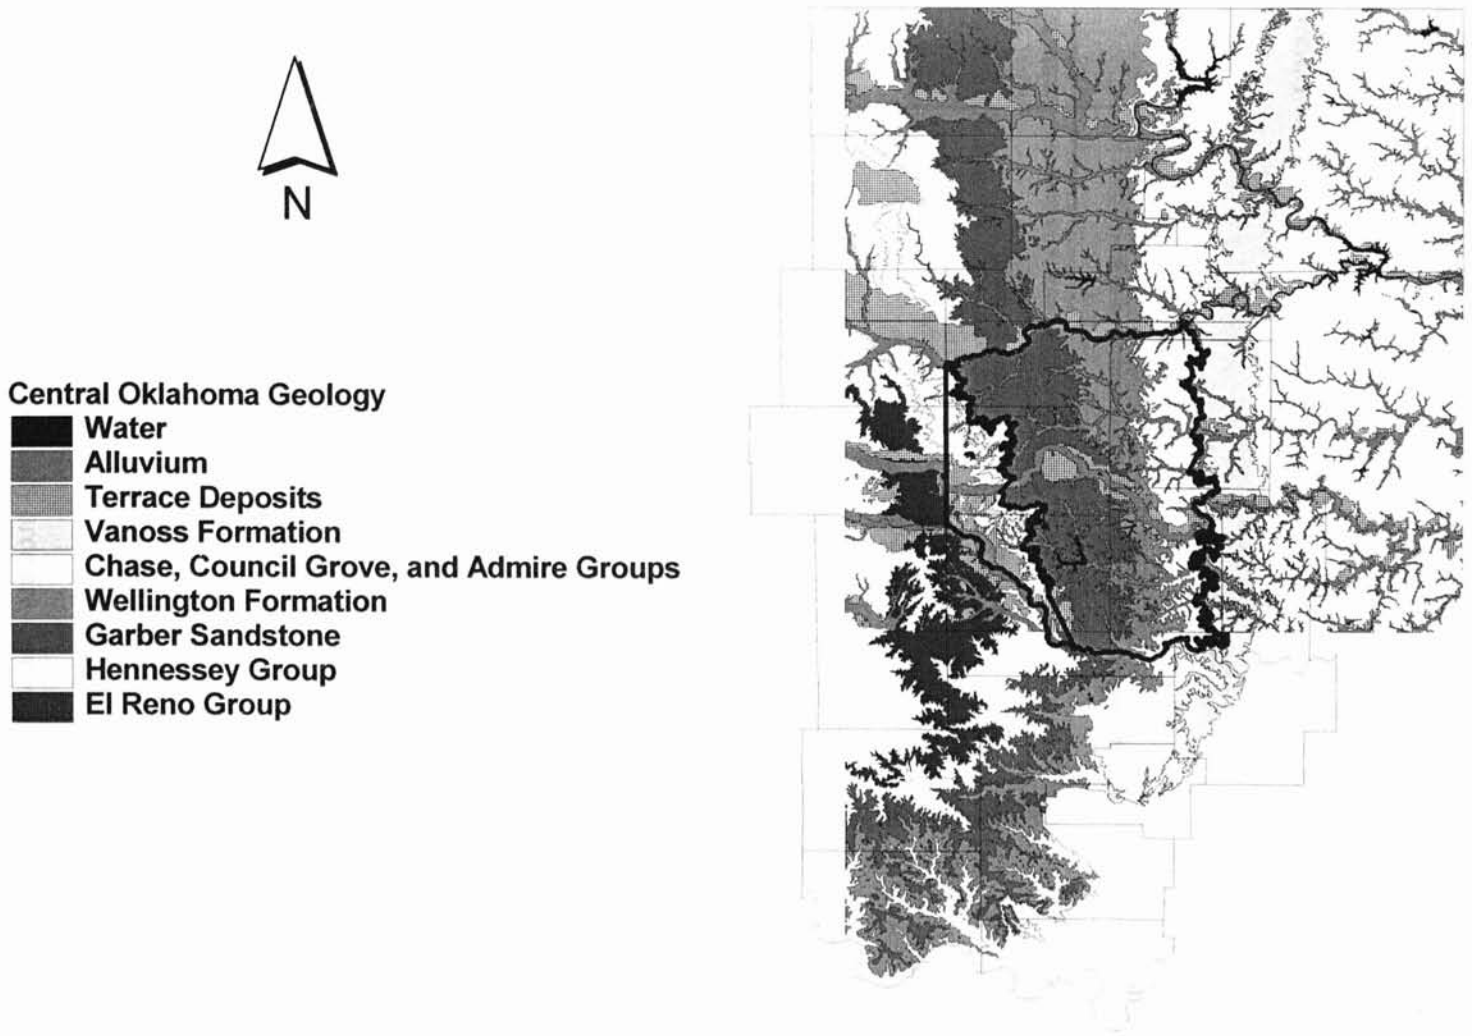

Figure 3. Generalized geologic map of central Oklahoma with aquifer boundaries.

Admire Groups, consisting of mudstone, fine-grained sandstone, and conglomerate, with a combined thickness of about 170 to 285 meters, comprise the eastern portion of the aquifer (Christenson, Morton, and Mesander, 1992). Finally, mudstone and a few thin beds of fine-grained sandstone compose the underlying Vanoss Formation (Figure 4; Breit, 1998).

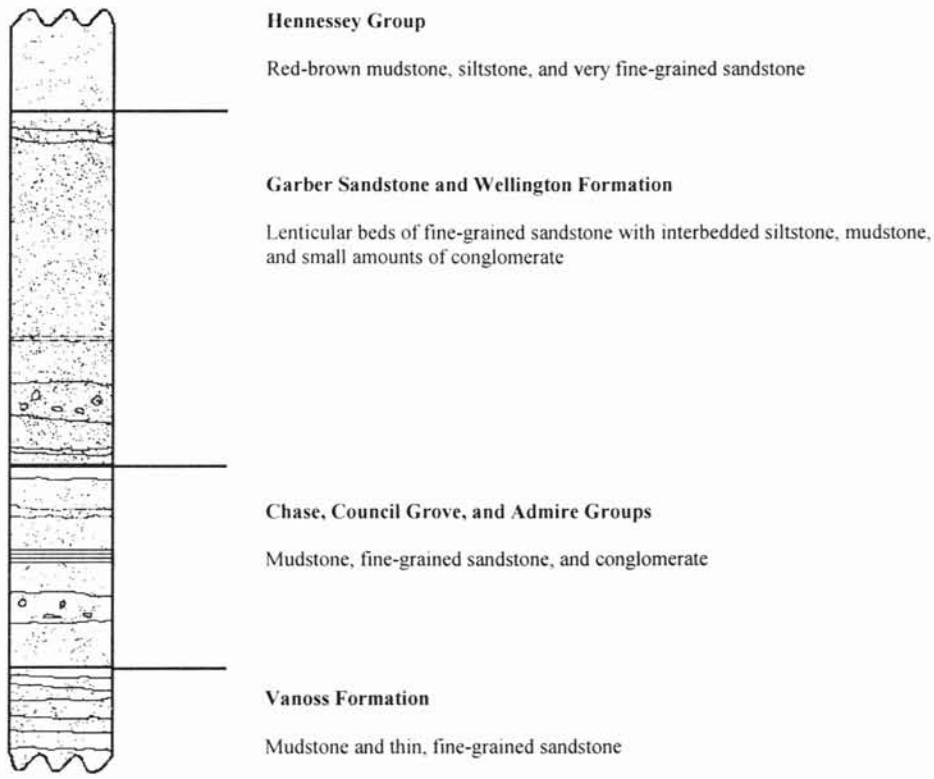

Figure 4. Generalized stratigraphic column of the Central Oklahoma aquifer (adapted from Breit,1998).

Petrology

Detrital Constituents. According to Witt (2001), the majority of the grains that compose the Permian rocks in the study area are monocrystalline quartz with minor amounts of plagioclase and rock fragments (carbonate, siltstone, chert, polycrystalline

quartz, and metamorphics); trace detrital constituents include muscovite, zircon, and tourmaline. Along with monocrystalline quartz, Breit (1998) indicates that illite comprises a major portion of the detrital constituents. Consistent with similar depositional environment, source unit, and burial history, the mineral assemblage is similar in all of the Permian units; therefore, one may class the sandstone in the aquifer as a sublitharenite (Folk, 1980).

Authigenic Constituents. Dolomite, quartz overgrowths, calcite, hematite, goethite, kaolinite, manganese oxides, and barite, common authigenic minerals, formed within the aquifer after deposition as pore filling cements, coatings on detrital grains, and, locally, to replace detrital grains; in addition, one finds small black zones (less than one centimeter) of rare authigenic minerals with large concentrations of selenium, uranium, and vanadium disseminated throughout the aquifer (Breit, 1998). Of particular interest are the authigenic minerals that give the rocks in the aquifer their red or yellow-brown color. Hematite, the mineral responsible for the red color, grains range from ultrafine pigment to specular. The yellow-brown iron oxides include goethite and other less crystalline phases that form ultrafine pigment and coatings on constituents such as, kaolinite, hematite, quartz overgrowths, and occasionally dolomite (Breit, 1998). Breit (1998) also detected large concentrations of arsenic in some yellow-brown iron oxides.

Diagenesis

Deposition. Deposition of the Permian beds began as rivers carried sediment west and north from the Ouachita uplift in the southeast toward the epeiric sea (Figure 5; Breit, 1998; Wicander, and Monroe, 1993). Generally dry conditions, with intermittent wet

periods that enhanced chemical weathering, are consistent with the bedded evaporite deposits west of the aquifer. Variations in hematite indicate an intricate reddening sequence (Witt, 2001). Periods of oxidation destroyed organic matter and minerals that were stable in reducing environments while producing the red color of the Permian beds (Table 4; Breit, 1998).

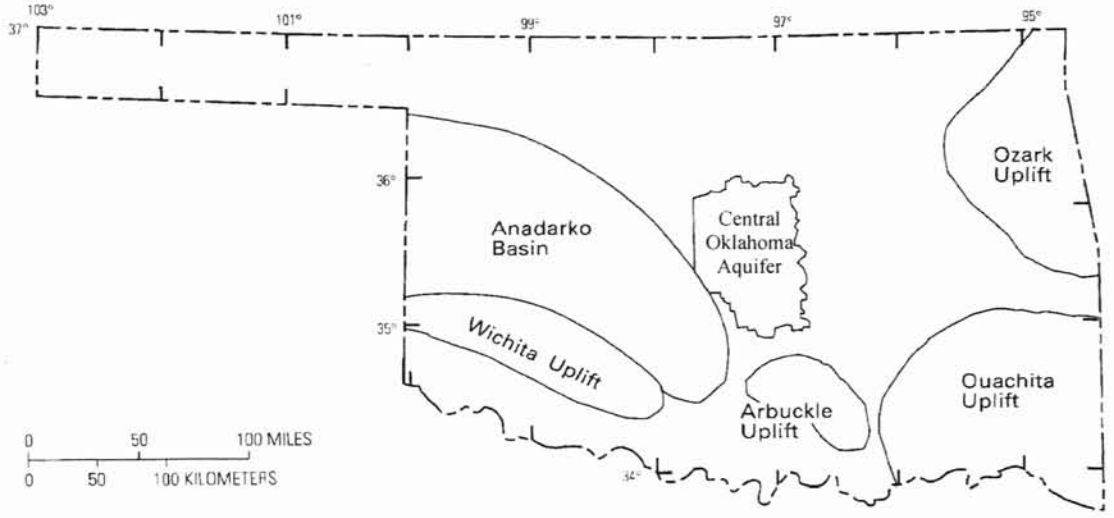

Figure 5. Approximate locations of Anadarko Basin and uplifts that affected deposition of the Permian rocks in the Central Oklahoma Aquifer (adapted from Breit, 1998).

Burial. Diagenetic activity began after shallow burial with precipitation of dolomite cement, quartz overgrowths, barite and some hematite. During this period, pore-water composition consisted of seawater altered by evaporation (Breit, 1998). Parkhurst, Christenson, and Breit (1993) assert that saline solutions found below the aquifer may be remnants of this pore-water.

Mineral	Sediment Deposition	Burial	Exposure
Dolomite	**Precipitation:** micritic cement; sparry dolomite in mudstone clasts	**Precipitation:** sparry dolomite cement; $\delta^{18}O$ consistent with seawater	**Dissolution:** pitted surfaces; voids within sparry crystals
Calcite	**Precipitation(?):** probably the original mineral in pedogenic nodules	**Dolomitization:** absence of early-formed calcite	**Precipitation:** after quartz overgrowths, $\delta^{18}O$ consistent with metoric water **Dissolution:** in shallow aquifer - voids within sparry cement, etch pits
Hematite	**Precipitation:** around burrows, oxidation of ferroan carbonates, oxidation of pyrite(?)	**Precipitation:** continued oxidation of ferroan silicates (biotite)	**Unknown**
Manganese Oxides	**Unknown:** probably formed by oxidation during pedogenesis	**Dissolution(?):** high manganese content of dolomite indicates reduction of manganese in oxides	**Precipitation:** cement of quartz grains, box-work after dolomite
Goethite	**Precipitation:** preserved in sparry dolomite cement and under quartz overgrowths, precipitated during pedogenesis?	**Recrystallization:** altered to hematite?	**Precipitation(?):** overgrowths on hematite, lining of voids that lack other cements; in outcrop, it is abundant near fractures
Kaolinite	**Precipitation:** discrete laminae in siltstone, inclusions in dolomite	**Unknown**	**Precipitation:** pore-filling clay on quartz overgrowths near dissolved feldspar
Quartz Overgrowths	**Unknown**	**Precipitation:** absence of overgrowths in dolomite-cemented rocks, inclusions of iron oxide, common beneath calcite cement	**Precipitation:** likely sink of silica released from dissolved framework silicates
Chert	**Detrital phase**	**Unknown**	**Dissolution:** voids with remnant texture that are surrounded by quartz rims, not compacted or filled by other minerals
Barite	**Unknown**	**Precipitation:** replacement of gypsum; formed after hematite; $\delta^{34}S$ values are consistent with Permian seawater	**Dissolution(?):** scattered prismatic crystals in pores are irregular and embayed
Feldspar	**Dissolution:** partially dissolved grains within dolomite cement	**Unknown**	**Dissolution:** skeletal grains within voids that are not compacted, or cemented

Table 4. Evidence for mineral alteration within Permian rocks in the Central Oklahoma aquifer. From Breit, 1998.

Exposure. Exposure and erosion during the Tertiary and Quaternary provided the opportunity for meteoric water, primarily from precipitation, to become the principal source of aquifer recharge. As meteoric water moves through the rock it dilutes and displaces the remnant saline water (Parkhurst, Christenson, and Breit, 1993). This recharge water also reacts with the solid phase materials; these reactions appear to favor oxidation, which leads to the formation of manganese oxide, goethite, and many other rare minerals (Breit, 1998).

Hydrogeology

The Central Oklahoma Aquifer consists of both confined and unconfined portions. Large amounts of mudstone and siltstone in the Hennessey allow one to consider it a confining unit for the western portion of the aquifer; however, the dip of the unit leaves the eastern portion exposed. The Pennsylvanian Vanoss Formation serves as the lower confining layer (Figure 6). Flow is greatest in the central portion of the aquifer where it is thickest and contains the highest percentage of sandstone. Also, flow is greater in the Garber Sandstone and Wellington Formation where wells typically produce 10 to 25 liters per second; whereas, the Chase, Council Grove, and Admire Groups typically produce 0.63 to 6.3 liters per second (Christenson, 1998).

Using median values for the aquifer properties Christenson, Parkhurst, and Breit (1998) developed a finite-difference groundwater flow model to simulate flow in the aquifer. Using transmissivity values of 24 to 42 square meters per day, a horizontal hydraulic conductivity of 1.4 meters per day, a ratio of horizontal to vertical hydraulic conductivity of 10,000, a porosity of .22, a storage coefficient of .0002, and a recharge

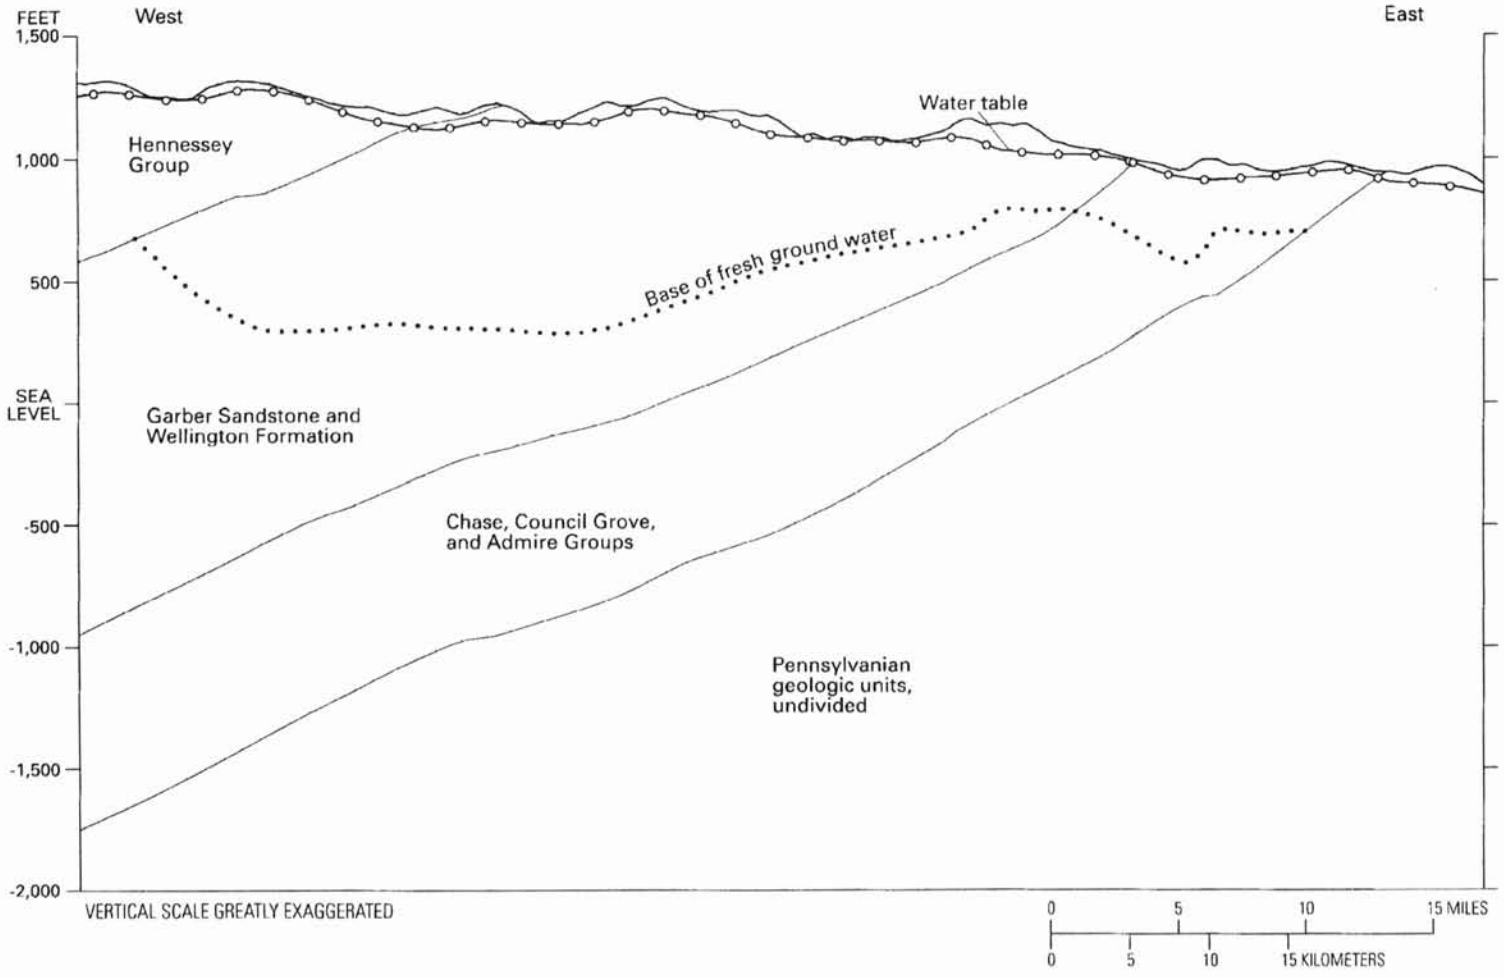

Figure 6. Cross-section through the Central Oklahoma Aquifer (from Christenson, 1998).

rate of 41 millimeters per year they identified three distinct flow systems: (1) shallow, unconfined; (2) deep, unconfined; and (3) deep, confined. Flux and aqueous geochemistry define these three systems.

Precipitation recharges groundwater in the shallow flow system where it travels along fairly short flow lines to discharge in the nearest stream; transit times are tens to hundreds of years. The rapid flux is responsible for removing most of the dolomite, calcite, and exchangeable sodium. Recharge along groundwater divides contributes to the deep flow system in the unconfined portion of the aquifer; transit times may exceed 5,000 years along some flow lines. While this lower flux is able to remove most of the exchangeable sodium, significant carbonate minerals remain. Finally, recharge from a small portion of the outcrop area and leakage from the Hennessey Group contribute to the deep flow system in the confined portion of the aquifer; transit times vary from thousands to tens of thousands of years. Flux is insufficient to remove either carbonate minerals or exchangeable sodium (Christenson, Parkhurst, and Breit, 1998). See Figure 7 for a representation of flow paths in the aquifer.

The above description of flow in the aquifer is accurate as long as the unstated, yet primary, assumption is accurate; namely, that the aquifer behaves solely as a porous and unfractured medium. Such an assumption is unlikely and though the model may serve well as a general guide, one must examine the fractures in detail. With large concentrations of arsenic located in some of the yellow-brown iron oxides found in the aquifer, and in goethite, that is abundant near fractures, one must examine how the fracture flow affects the distribution and occurrence of arsenic.

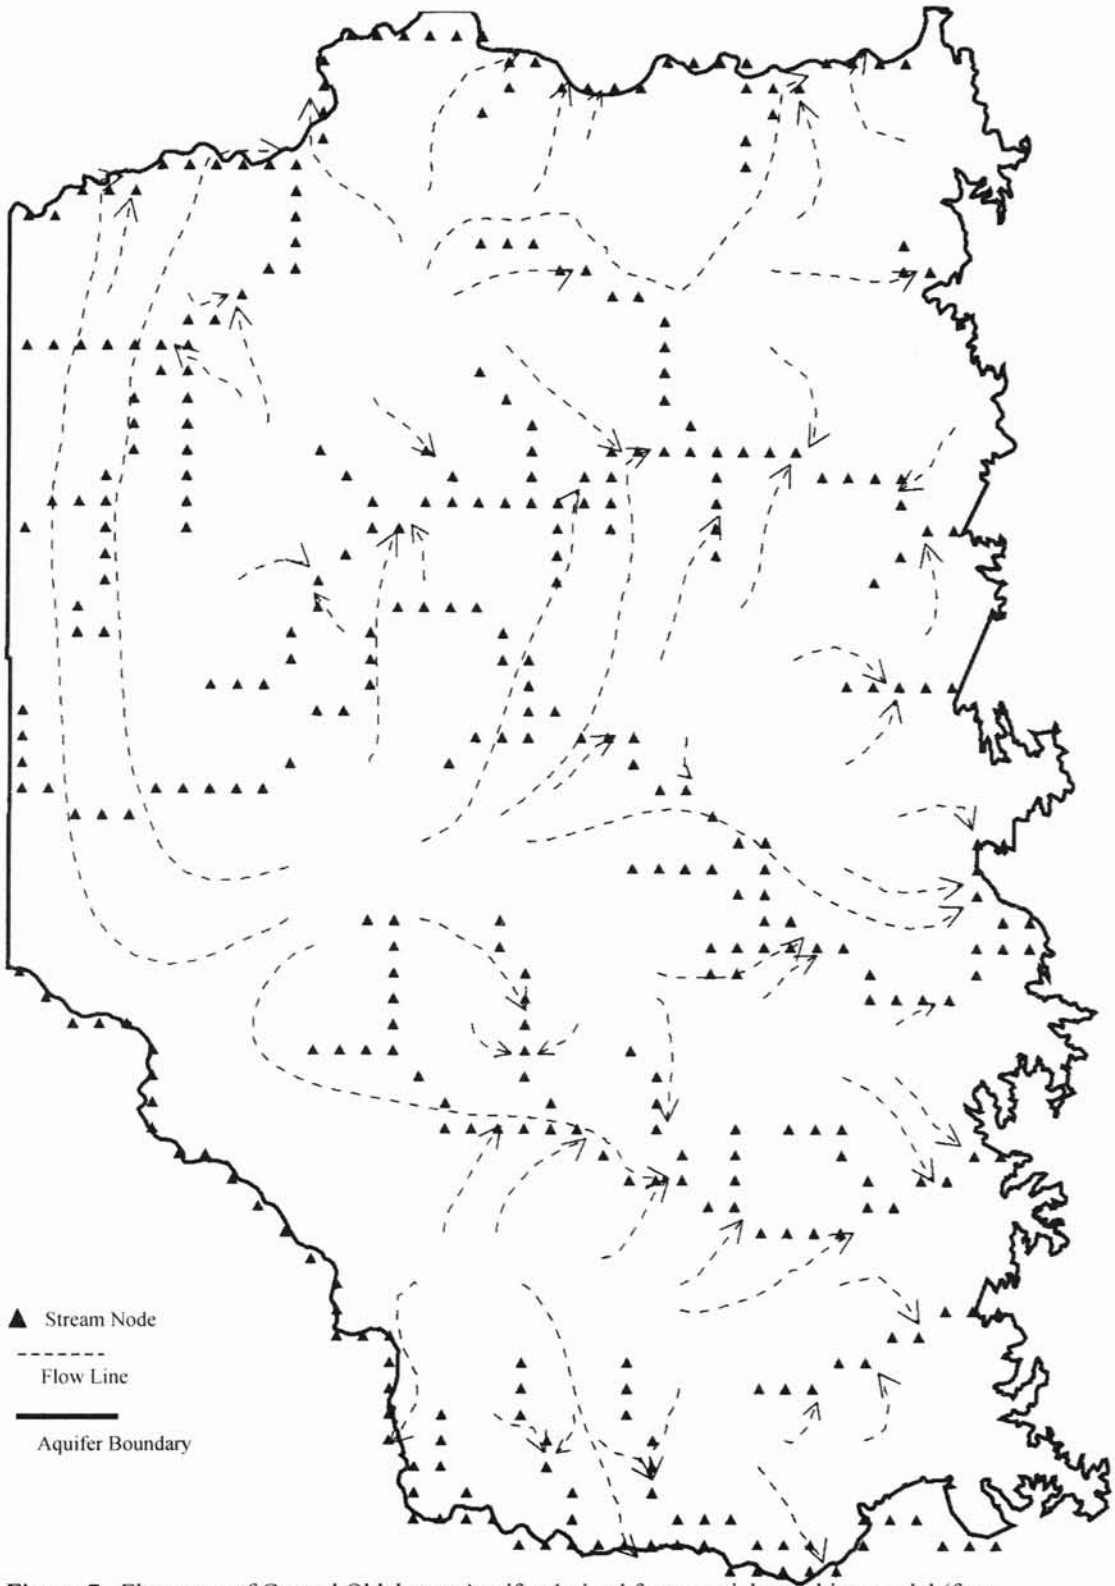

Figure 7. Flow map of Central Oklahoma Aquifer derived from particle-tracking model (from Christenson, Parkhurst, and Breit, 1998)

CHAPTER THREE

AQUEOUS GEOCHEMISTRY

Major-Ion Geochemistry

For the purpose of this section, the writer chose to eliminate several analyses from evaluation, primarily those located in the northwest quadrant of the study area. The writer removed these data because of dubious reliability, as documented in appendix B, or unreported values of major ions and insufficient data to estimate values necessary for calculations. As the primary purpose of this paper is to investigate arsenic in the Central Oklahoma Aquifer, editing does not distract significantly from that endeavor.

Using templates from Back (1961) (Figure 8), analyses from the shallow unconfined zone of the aquifer group in the bicarbonate range on the anion facies and the calcium-sodium range of the cation facies (Figure 9). Calcium, magnesium, and carbonate dominate the chemical signature of water in this zone, however, one observes a trend toward the sodium apex of the cation triangle. This trend indicates that some ion exchange is taking place (Hounslow, 1995).

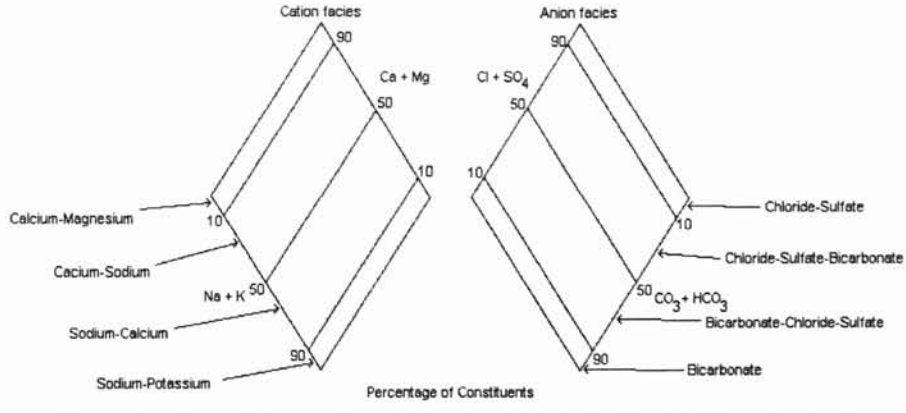

Figure 8. Templates for classifying waters into facies for cations and anions (from Domenico and Schwartz, 1998)

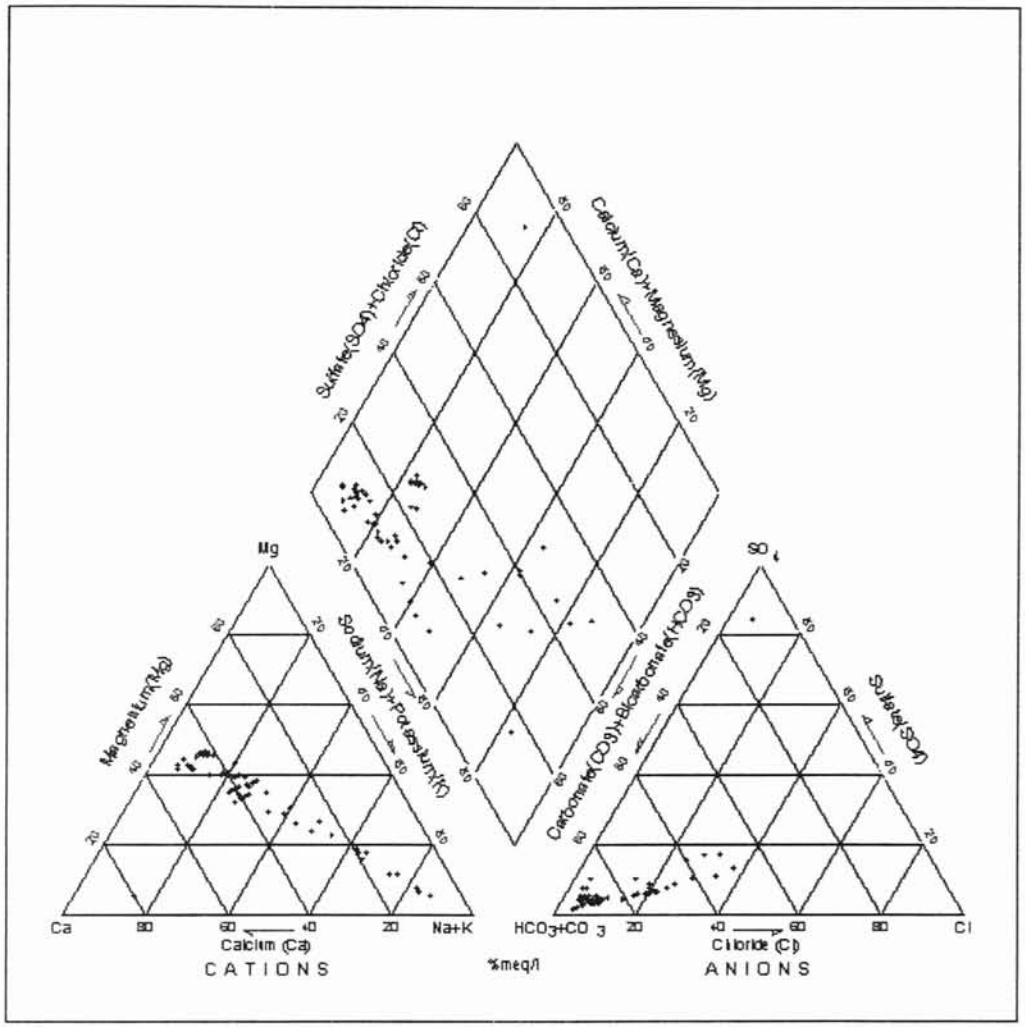

Figure 9. Piper plot of the shallow unconfined zone.

In the deep unconfined zone, one notices a grouping of samples similar to the shallow unconfined zone (Figure 10). While the samples continue to plot in the bicarbonate range of the anion facies, they tend to shift toward the calcium-magnesium range of the cation facies. Decreased flux is probably responsible for this shift. The pattern of the cation triangle indicates continuing ion exchange with an increase in dissolved sodium relative to calcium and magnesium. However, the plots of both

toward the carbonate apex of the anion triangle and toward the magnesium side of the cation triangle indicate carbonate weathering is the primary source of dissolved solids in these samples.

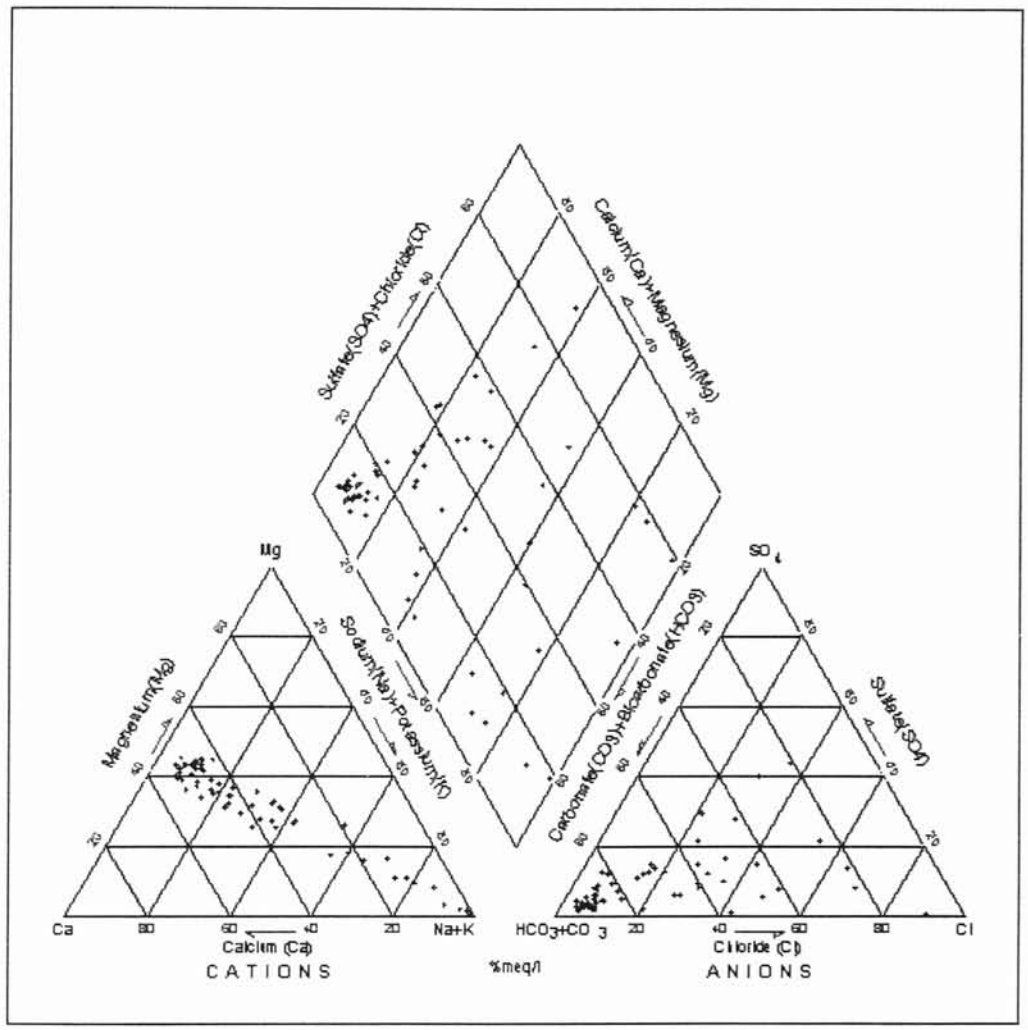

Figure 11. Piper plot of the unconfined zone, unreported depths.

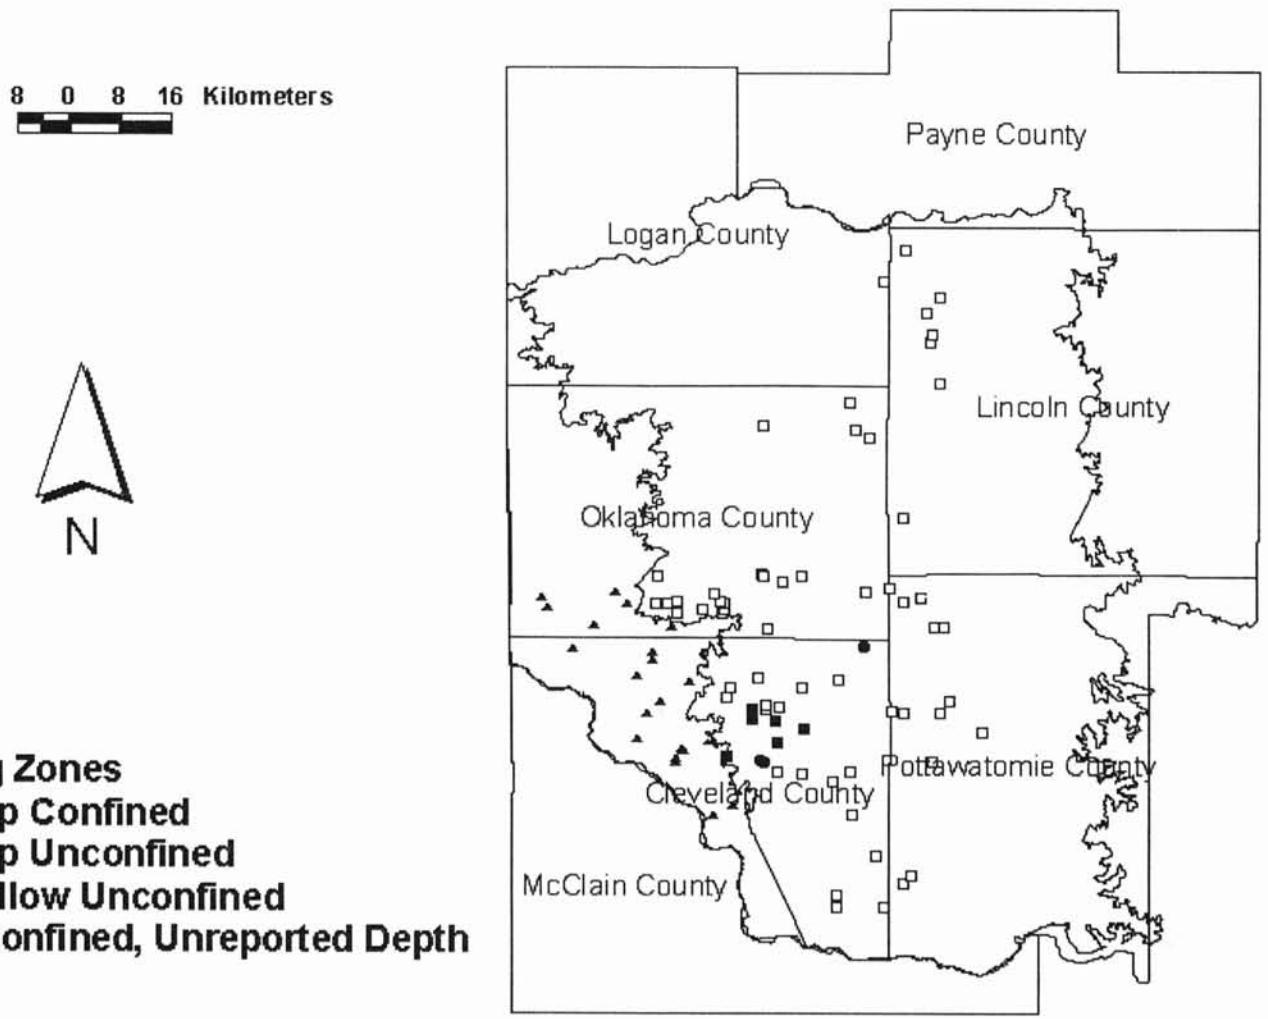

Figure 12. Map illustrating the location of wells and sampling zones in the Central Oklahoma Aquifer.

Finally, one observes a dramatic change in the chemical analyses in the deep confined portions of the aquifer (Figure 13). Analyses from the confined zone group in the lower apex of the diamond; that is, they group in the bicarbonate region of the anion facies and the sodium-potassium region of the cation facies. This change is likely a result

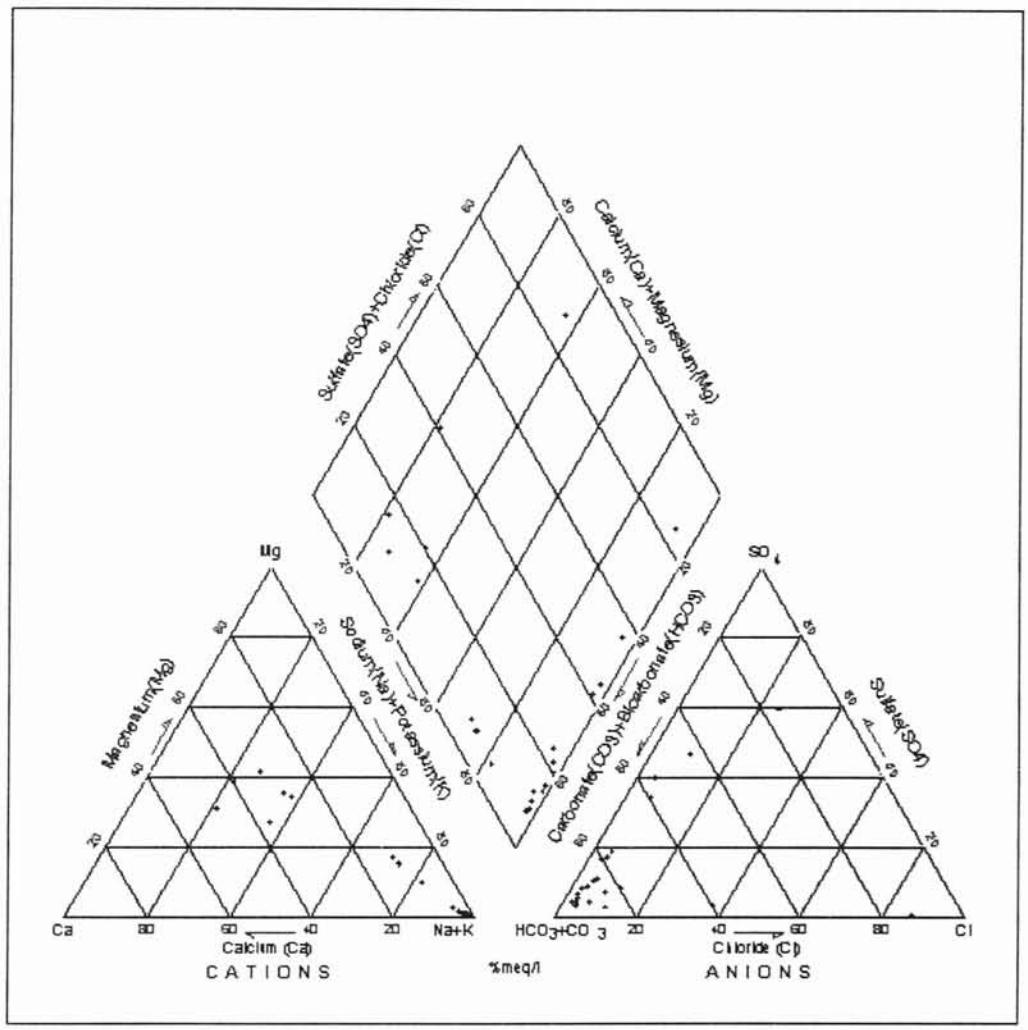

Figure 13. Piper plot of the deep confined zone.

of the low flux in the deep confined zone. Breit (1998) suggests remnants from an epeiric sea may be partly responsible for the increased sodium concentrations.

Christianson (1998) illustrates (Figure 6) the base of fresh water, determined by total dissolved solids, as a fluctuating line through the aquifer. However, that diagram may mislead if one does not examine the areal distribution of total dissolved solids (Figure 14). The map indicates a group of high total dissolved solids samples, as expected, in the west-central portion of the study area; however, samples in the south-central and some in Logan county are high as well. Furthermore, some wells, such as well number 352703097302401, in the Garber Sandstone average high total dissolved solids levels regardless of depth.

Naturally Occurring Trace Elements

Nearly all trace elements occur, to some extent, in the Central Oklahoma Aquifer (see appendix C). Predominate ions are barium, boron, iron, and fluoride. One commonly finds barite ($BaSO_4$) as roses, which likely formed by the reaction of barium with sulfate in the epeiric sea. Dissolved fluoride probably originates from the weathering of fluorite (CaF_2) and boron from the weathering of evaporite deposits.

Iron is the most readily perceived constituent in the aquifer. When approaching most outcrops one immediately sees the distinctive reddish-brown color of hematite (Fe_2O_3). Witt (2001) demonstrates how hematite constitutes a considerable portion of the aquifer and how it is associated with other iron hydroxides.

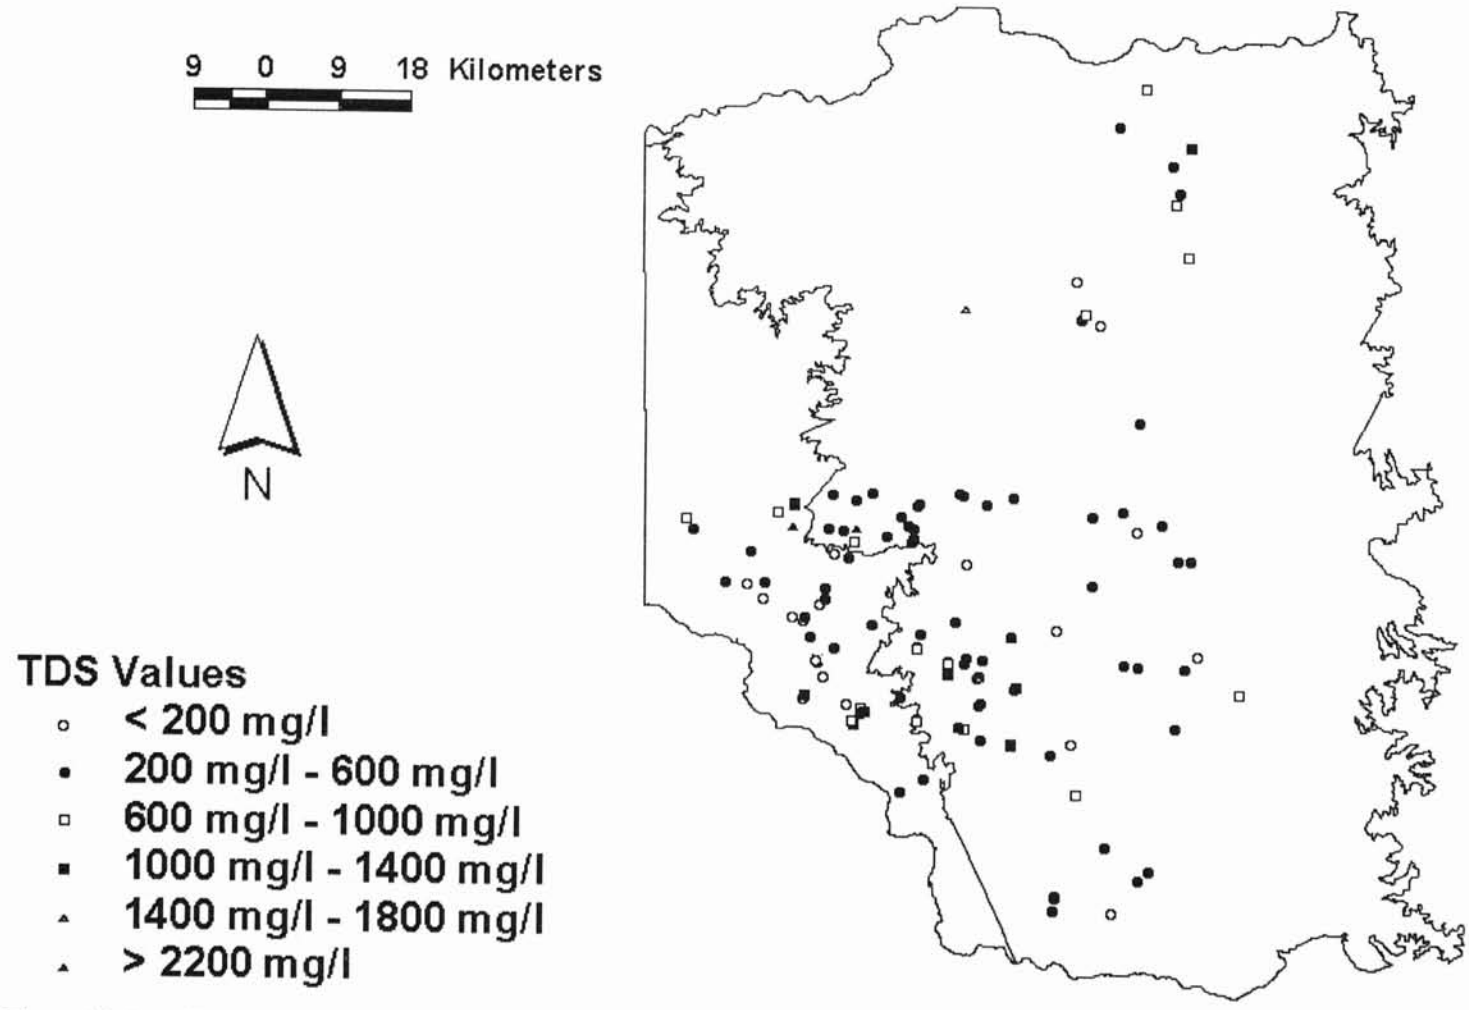

Figure 14. Map illustrating total dissolved solids levels in the Central Oklahoma Aquifer.

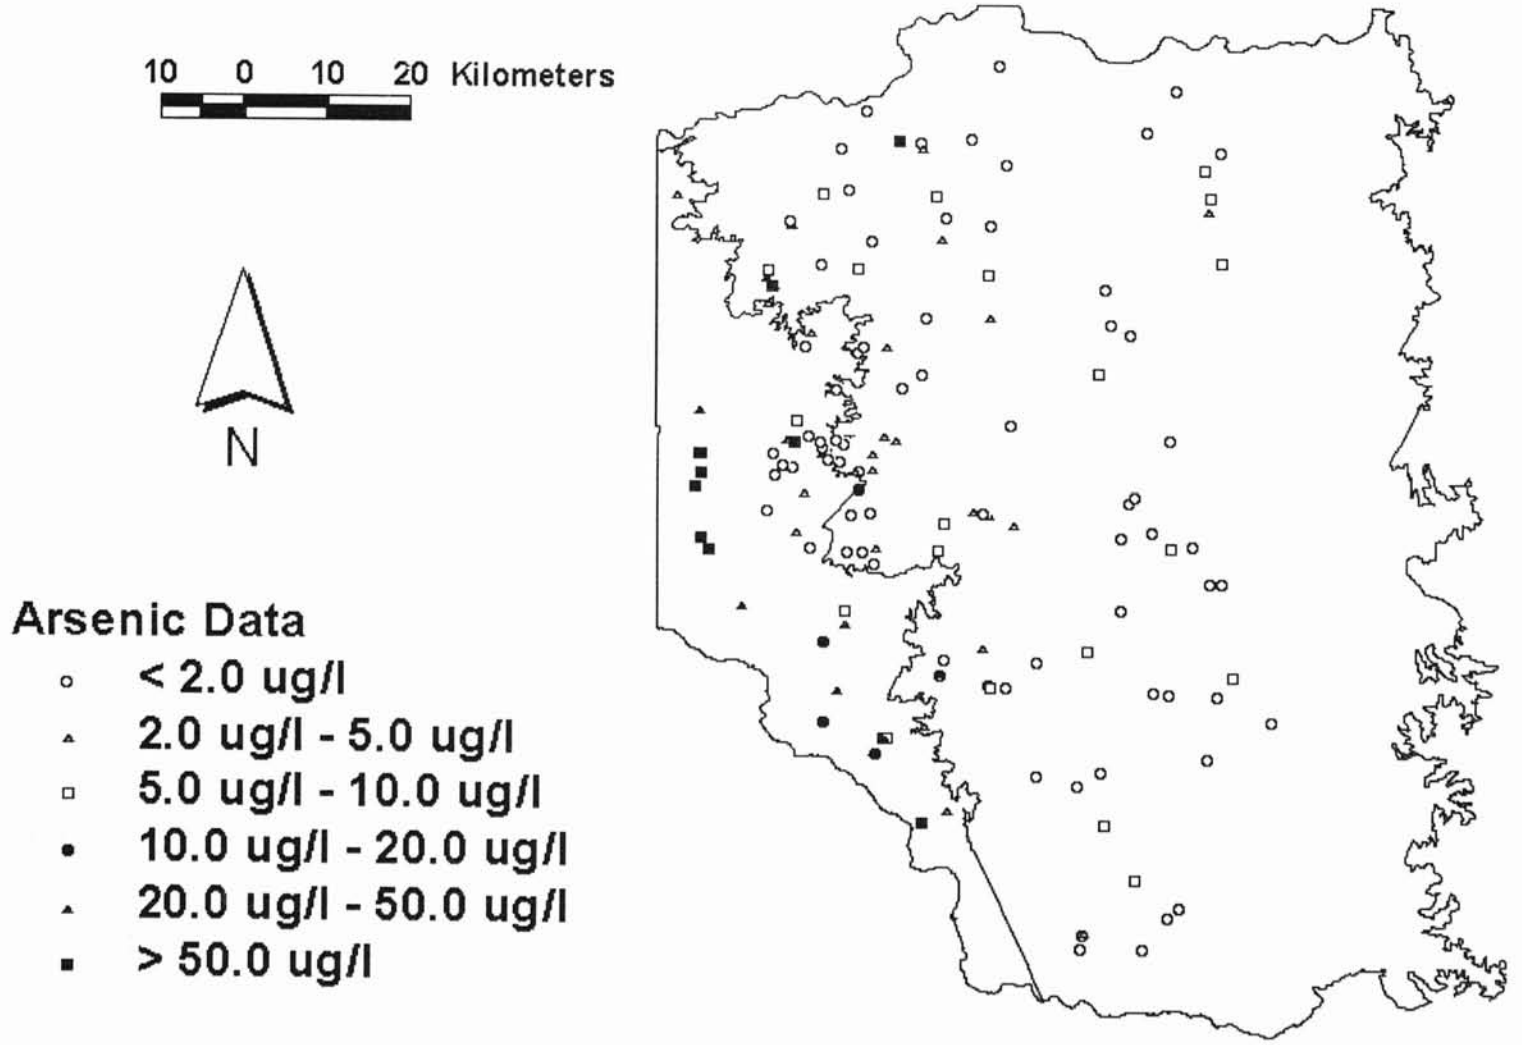

Figure 15. Map illustrating arsenic concentrations in the Central Oklahoma Aquifer.

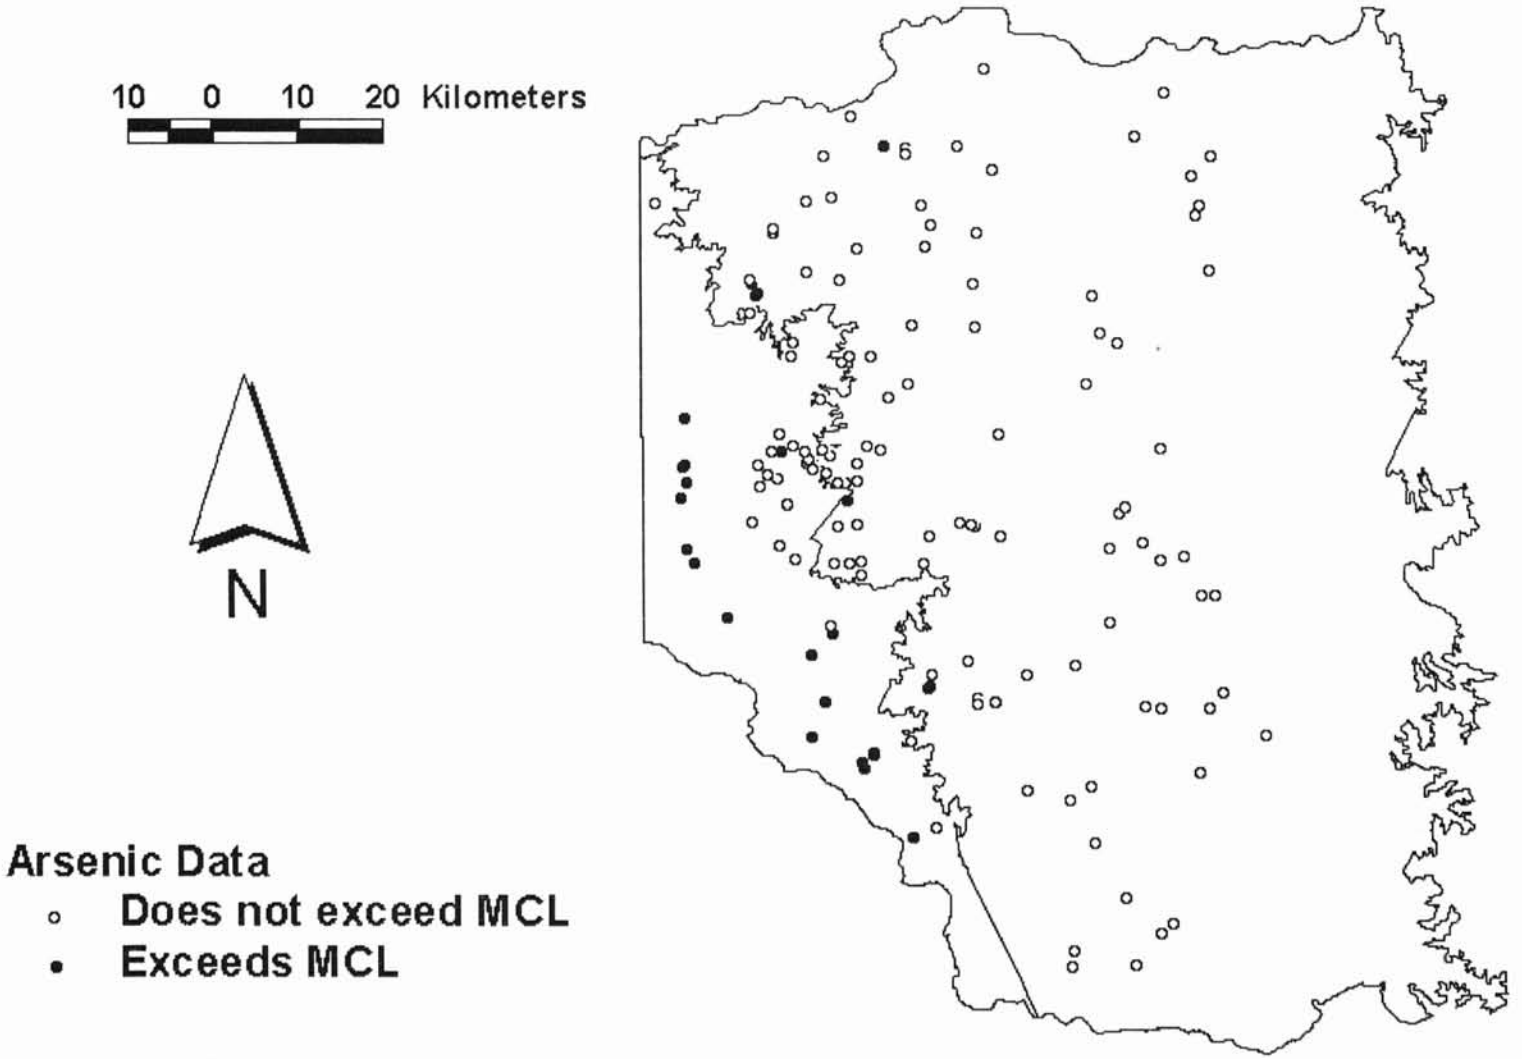

Figure 16. Map illustrating locations that exceed the Environmental Protection Agency's maximum contaminant level in the Central Oklahoma Aquifer.

Arsenic

Arsenic is a group 15 element with an atomic number of 33, an atomic weight of 74.92, one natural isotope ^{75}As, and four important oxidation states –3, 0, +3 (arsenite), and +5 (arsenate) (Ayres and Hellier, 1998). It is 52nd in abundance among the earth's mineral species with a crustal concentration of approximately 1.8 parts per million (Krauskopf and Bird, 1995). In addition, one finds arsenic in most fresh water.

Distribution

One finds arsenic distributed throughout the Central Oklahoma Aquifer (Figure 15); however, concentrations exceeding the MCL of 10 µg/l are primarily in the western confined zone (Figure 16). Most samples that surpass the MCL are from depths greater than 90 meters (Figure 17). Also, one finds elevated arsenic concentrations associated with high total dissolved solids (Figure 18); that is, samples where the arsenic concentrations go beyond the maximum contaminant level, the total dissolved solids are over 400 mg/l. In addition, raised arsenic concentrations appear to favor high pH areas (Figure 19).

The distribution of arsenic implies that water must travel through a large volume of rock to accumulate large concentrations of the element. Stiff diagrams for the collected water samples (Figure 20) support this implication. The sodium-bicarbonate waters of the deep confined portions of the aquifer are consistent with the flow regimes mentioned in chapter two; that is, there is insufficient flux to remove either the carbonate minerals or the exchangeable sodium. *Prima facie* there may be a relation between

sodium-bicarbonate water and arsenic concentration, however, arsenic levels are likely influenced more by pH and total dissolved solids.

Source

Realgar (AsS) and orpiment (As_2S_3) are minerals associated with hydrothermal deposits (Klein, 1993). Orogenic activity during the late Mississippian and Pennsylvanian periods subdivided Oklahoma into various tectonic provinces and exposed igneous rocks to weathering (Johnson, 1991). During formation of these pre-Cambrian and Cambrian igneous rocks, precipitation of trace amounts of arsenic, gold, silver, and lead minerals was likely. Eh-pH diagrams indicate that realgar and orpiment are stable only in a reducing environment (Figure 21). Therefore, as the orogenic movements transpired, exposing these deposits to oxic weathering conditions, the arsenic probably oxidized and dissociated from the sulfur to form arsenic acid (H_3AsO_4). The arsenic traveled with sediments that helped fill the Anadarko Basin (Johnson, 1991).

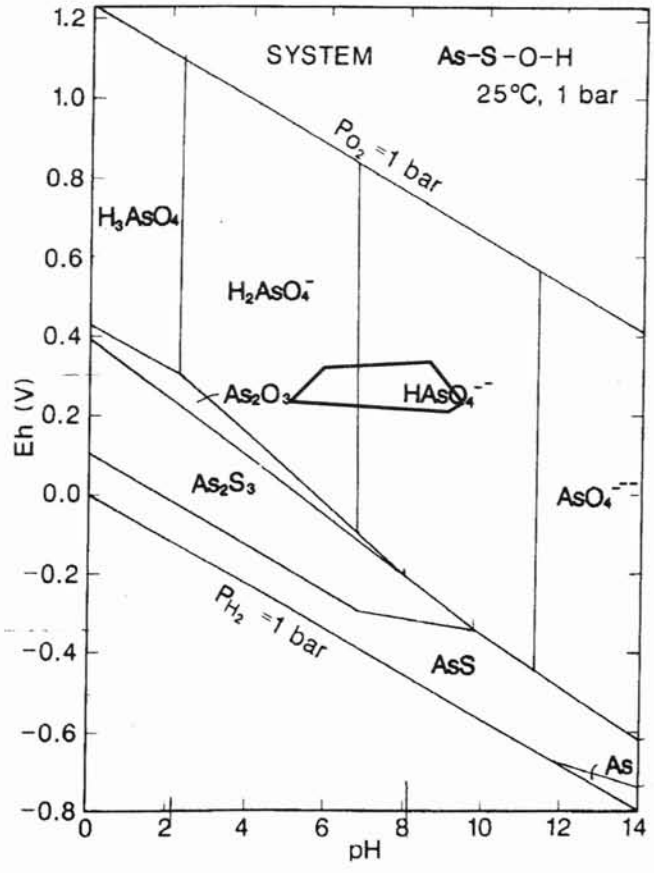

Figure 21. Eh-pH diagram for part of the system As-S-O-H at $\alpha_{As} = 10^{-6}$ and $\alpha_S = 10^{-3}$ (from Brookins, 1988).

Plot of arsenic samples from Central Oklahoma Aquifer water analyses.

Sediments continued to fill the basin trapping some of the arsenic. Petroleum began to precipitate in porous rocks of the basin (Ferguson, 1977). Petroleum formation may have created a reducing environment that altered some of the arsenic acid to arsenious acid (H_3AsO_3) (Figure 22). Trace concentrations of arsenic are common for petroleum deposits (Hoffstader, 1976; Dekkers, 1999).

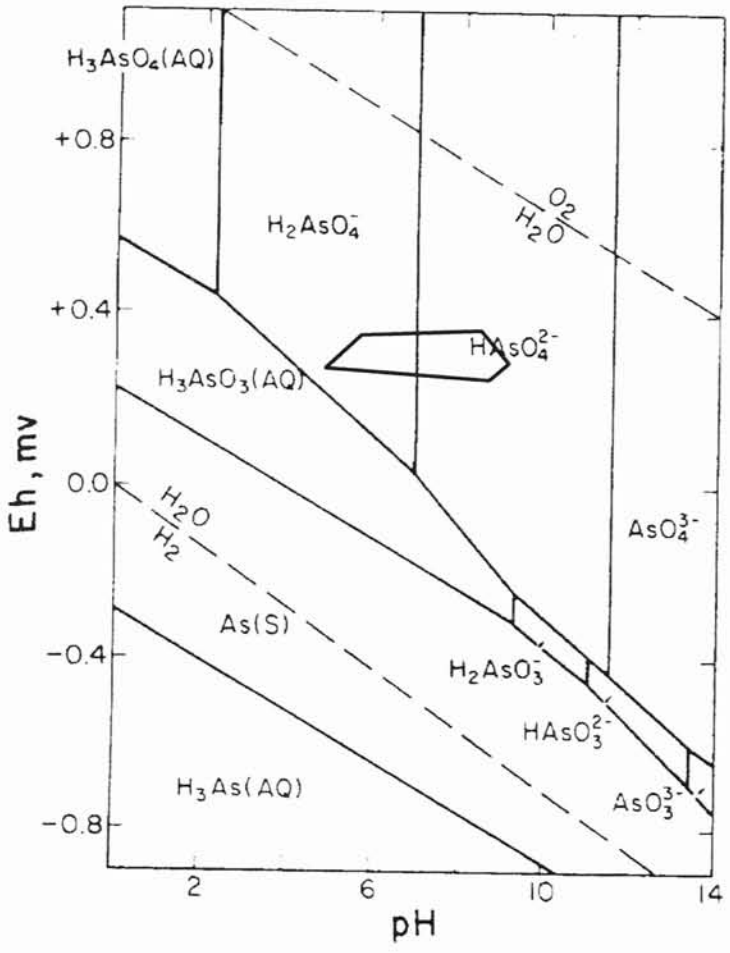

Figure 22 Eh-pH diagram of the arsenic-H_2O system at $\alpha_{As} = 10^{-3}$ (from Dove and Rimstidt, 1985).

Plot of arsenic samples from Central Oklahoma Aquifer water analyses.

As these petroleum deposits grew, they began forcing connate water, with hydrocarbons, up and toward the margins of the basin. The water migrated from the Pennsylvanian strata to the Permian through high angle faults in the region. The hydrocarbons then precipitated from solution in the saline waters of the overlying

Permian rocks, reacting with the sulfate in those waters to produce carbonate cement and hydrogen sulfide (H_2S) (Ferguson, 1977).

As the reaction proceeds, the hydrogen sulfide begins reacting with iron oxide to produce pyrite (FeS_2) (Lilburn and Al-Shaieb, 1983):

$$2H_2S + Fe_2O_3 \longleftrightarrow FeS_2 + 2H_2O + FeO \qquad (4.1)$$

From the Eh-pH diagram for the system Fe-S-O-H, one observes that pyrite is only stable under reducing conditions (Figure 23). Cherry, et al. (1979) demonstrate how hydrogen sulfide can reduce arsenate to arsenite when it is the only dissolved species available to cause the alteration. It is, therefore, reasonable, from the Eh-pH diagram for the system As-Fe-O-H-S and from Cherry, et al. (1979), for hematite and arsenious acid to exist in the same environment (Figure 24).

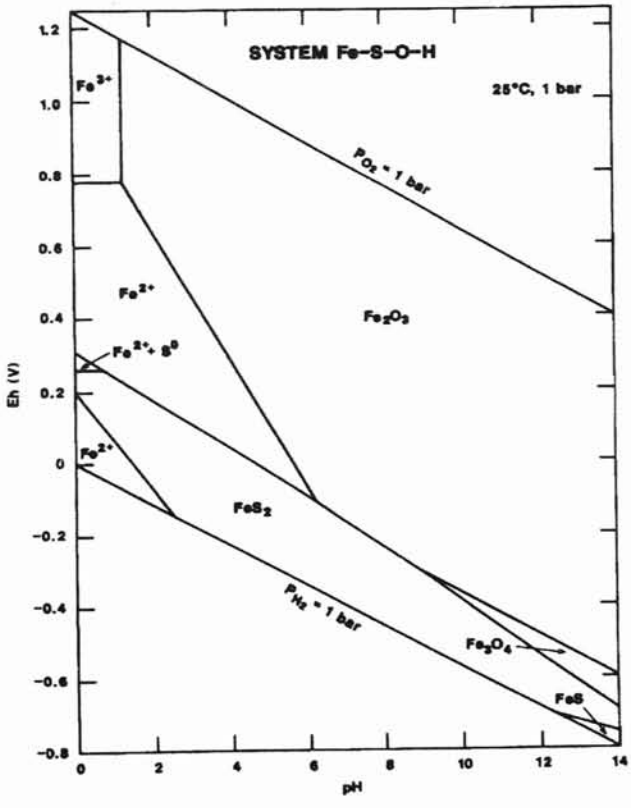

Figure 23. Eh-pH diagram for part of the system Fe-S-O-H at $\alpha_{Fe} = 10^{-6}$ and $\alpha_S = 10^{-3}$ (from Brookins, 1988).

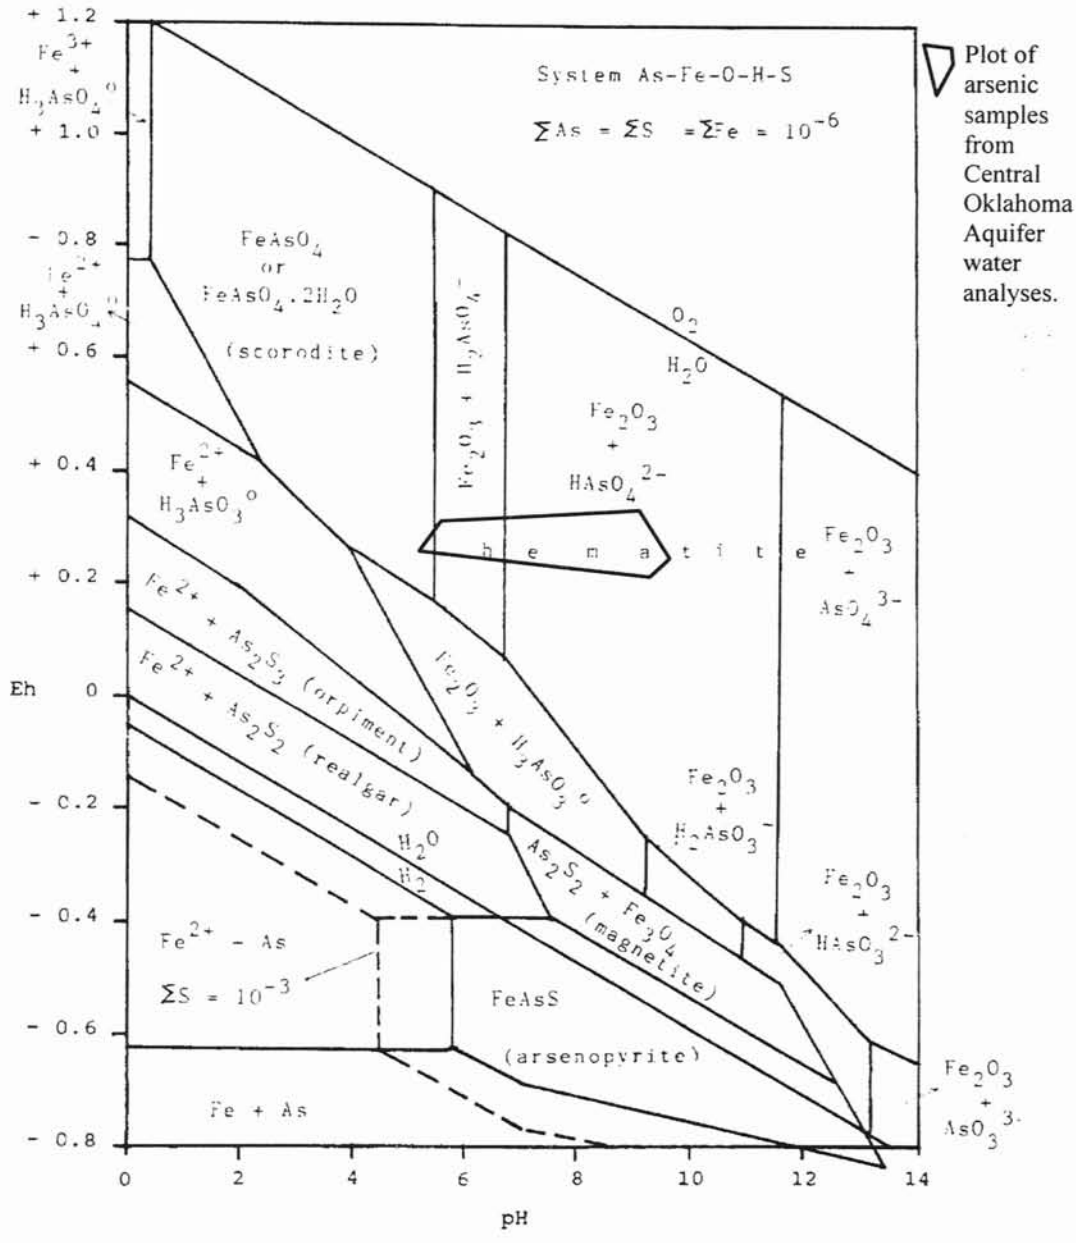

Figure 24. Eh-pH diagram for the system As-Fe-O-H-S, (from Vink, 1995).

As the deformation and weathering begins to expose the Permian rocks to meteoric waters and oxidizing conditions, the pyrite begins to oxidize (Hounslow, 1995):

$$FeS_2 + 3.75O_2 + 2.5H_2O \longleftrightarrow FeOOH + 2SO_4^{2-} + 4H^+ \qquad (4.2)$$

This reaction creates locally low pH allowing the oxidation of Fe^{2+} to Fe^{3+}. Simultaneously, arsenite oxidizes to form arsenate. It is then likely that some of the iron quickly reacts with the arsenate to form scorodite ($FeAsO_4 \cdot 2H_2O$):

$$Fe^{3+} + H_3AsO_4 + 2H_2O \longleftrightarrow FeAsO_4 \cdot 2H_2O + 3H^+ \quad (4.3)$$

Combining equation 4.2 and 4.3 and incorporating the oxidation of arsenite one finds the following reaction:

$$H_3AsO_3 + FeS_2 + 4.25O_2 + 2.5H_2O \longleftrightarrow FeAsO_4 \cdot 2H_2O + 2SO_4^{2-} + 4H^+ \quad (4.4)$$

As pH continues to rapidly rise, scorodite breaks down to form goethite (FeOOH) and arsenic acid (Dove and Rimstidt, 1985):

$$FeAsO_4 \cdot 2H_2O \longrightarrow FeOOH + H_2AsO_4^- + H^+ \quad (4.5)$$

In this state, the element may easily adsorb on hematite and goethite surfaces as Schlottmann, Mosier, and Breit (1998) suggest. Also, arsenate oxyanions will form an inner sphere complex with an iron-oxide surface (Schlottmann, Mosier, and Breit, 1998; after Davis and Kent, 1990).

Throughout the aquifer, one finds an abundance of goethite in the yellow-brown sandstones (Breit, 1998). Ferguson (1977) explains these yellow-brown sandstones by alteration from migrating oil field brines and hydrocarbons. Breit (1998) also points out that one finds considerable amounts of yellow-brown iron oxides along small fractures visible in some outcrops. Scanning electron microscope examinations of the yellow-brown iron oxides of the Central Oklahoma Aquifer reveals large concentrations of arsenic (Breit, 1998).

Mobilization

Scorodite is only stable when pH is less than 1.5 and arsenate activities greater than 0.1. At arsenate activities less than 0.01, scorodite is metastable and dissolves to iron hydroxide and arsenate ion solutions (Dove and Rimstidt, 1985). Calculating the arsenate activity in the Central Oklahoma Aquifer, using Equation 4.6 after Dove and Rimstidt (1985), one finds values well outside the scorodite stability field.

$$\alpha_{AsO_4^{3-}} = \frac{As_{Total}}{1 + \frac{\alpha_{H^+}}{K_3} + \frac{(\alpha_{H^+})^2}{K_2K_3} + \frac{(\alpha_{H^+})^3}{K_1K_2K_3}} \qquad (4.6)$$

$\alpha_{H^+} = 10^{-pH}$

As_{Total} = Arsenic concentration in solution (mmol/l)

K_1, K_2, K_3 = Hydrolysis constants of arsenate species given in table 5

Arsenate	pK
$H_3AsO_4 = H_2AsO_4^- + H^+$	2.24
$H_2AsO_4^- = HAsO_4^{2-} + H^+$	6.86
$HAsO_4^{2-} = AsO_4^{3-} + H^+$	11.49

Table 5. Hydrolysis constants of arsenate (from Dove and Rimstidt, 1985 after Wagman, 1982).

Aquifer conditions readily promote the transformation of scorodite to goethite as Equation 4.5 shows. The decay releases arsenate into the ground water where it follows flow paths described in chapter two. Schlottmann, Mosier, and Breit (1998) indicate that an oxidizing ground water with a high pH may mobilize the adsorbed arsenic as well. The arsenic then appears to concentrate in areas where flux is lowest.

Relation of Iron and Arsenic Concentrations

From the equations presented thus far, one notices a relationship between iron and arsenic. As expected, arsenic concentrations tend to increase as total dissolved solids increase. However, as total iron concentrations increase, arsenic concentrations decrease.

Examining the relationship of iron and arsenic to pH, one readily observes that as pH decreases, concentrations of both species likewise decrease (Figures 19, 25, and 26). This may represent that as the solution approaches the stability field of scorodite some precipitation occurs. Vogels and Johnson (1998) demonstrate that even at pH of 7 to 8, with high iron concentrations, some scorodite along with ferric oxyhydroxides will precipitate.

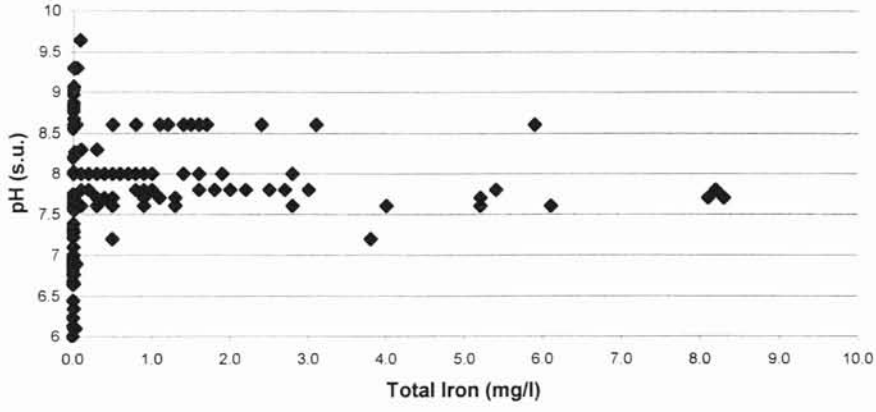

Figure 25. Iron concentration (all samples) versus pH.

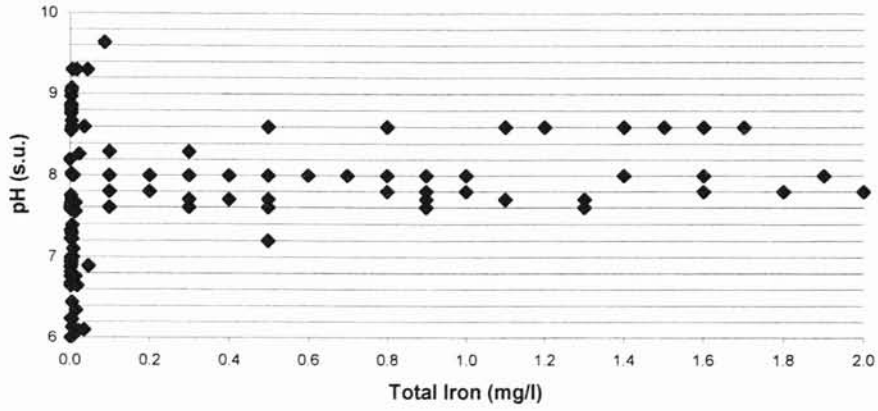

Figure 26. Iron concentration (samples < 2 mg/l) versus pH.

The research by Vogels and Johnson (1998) uses Fe^{6+} to maximize oxidation and production of scorodite for water treatment purposes:

$$Fe^{2+} + AsO_4^{3-} \longleftrightarrow FeAsO_4^{-} \xrightarrow{FeO_4^{2-}} FeAsO_{4(S)} + FeO(OH)_{(S)} \qquad (4.7)$$

However, Equation 4.7 and the Eh-pH diagram for the As-Fe-O-H-S (Figure 24) system suggest that under slightly acidic and oxic conditions some precipitation will take place. Such conditions are likely in areas of the aquifer. Figure 27 illustrates how shallow areas tend to have a lower pH. These shallow zones may be more oxic as they are under the influence of metoric waters.

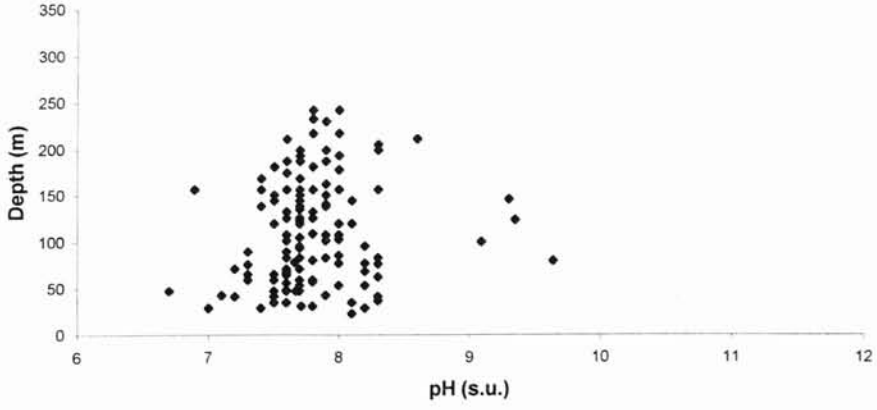

Figure 27. pH versus depth.

CHAPTER FOUR

SUMMARY AND CONCLUSION

Arsenic concentrations in the Central Oklahoma Aquifer exceed the maximum contaminant level of 10 μg/l. The implementation of the lower maximum contaminant level created a similar issue for many aquifers in the United States, especially those with red beds. The focus of this study was to examine the distribution, source, and mobilization of arsenic in the Central Oklahoma Aquifer.

One finds arsenic distributed throughout the aquifer, though typically at low concentrations. Elevated quantities occur primarily in the western deep confined zone. One also finds locally high concentrations in Logan County around the city of Edmond.

The source of arsenic is likely from hydrocarbon and connate water migration. Reactions between hydrogen sulfide and hematite produce pyrite in the Permian rocks. As pyrite decomposes, the products may react with arsenic acid to produce scorodite. Decomposition of scorodite would then produce goethite and releases arsenate into the ground water.

Low arsenate activities promote the freeing of arsenate. Additionally, high pH and oxidizing conditions mobilize adsorbed arsenic species. The mobilized arsenic then appears to travel along flow paths where it concentrates in areas of decreased flux.

Iron serves an important role with arsenic in the aquifer. As iron concentrations increase, arsenic concentrations tend to decrease. This relationship appears to be directly related to the pH of the ground water; that is, as the pH increases, concentrations of the species increase.

Further research of the Central Oklahoma Aquifer is necessary. Examination of aquifer rocks for distinct mineral species could establish certainty of the arsenic source. Examination of brines in deep portions of the Garber Sandstone, west of the study area, could confirm flow paths and concentration of arsenic. Furthermore, examination of fractures, which may act as conduits for ground water flow, may help increase understanding of the genesis of yellow-brown iron oxides associated with fractures in outcrop.

VITA 2

Michael Riley Keester

Candidate for the Degree of

Master of Science

Thesis: ARSENIC IN THE CENTRAL OKLAHOMA AQUIFER

Major Field: Geology

Biographical:

Personal Data: Born in Bakersfield, California on June 29, 1972 the son of riley and Nina Keester.

Education: Graduated from North Bakersfield High School, Bakersfield, California in May 1990; received Bachelor of Arts degree in Philosophy and Religion from Oklahoma Baptist University, Shawnee, Oklahoma in December 1996. Completed the requirements for the Master of Science degree with a major in Geology at Oklahoma State University in December 2002.
