PREFACE

This study was initiated in the fall of 1980. During the summer of 1981 field work began, but due to some difficulties only preliminary work could be done. In the following summer of 1982, the major part of my research began and I really began to observe the relationships in these species, despite technical difficulties which resulted in few numerical data. Sampling and measuring of herbarium specimens led to analyses that highly supported what I had observed both in the field and greenhouse. There is still considerable opportunity for research, as many facets of these species are still not fully understood; for example, reproduction. I suspect that further investigations will confirm the conclusions of this investigation.

I would like to express my appreciation to those who have served on my committee, Dr. James K. McPherson, Dr. Stanley Fox, and Dr. Arthur J. Pollard, for their advice and assistance during this study.

Thanks go to all who have assisted me during my studies--those who helped with the collections, computer, statistics, greenhouse work, and other tasks necessary in this investigation. Also, special thanks to Elizabeth deBoor for the illustrations of the plants and floral parts.

A special thanks is to be given to Tim Springer whose friendship and support, botanical expertise, and computer familiarity, and statistical analyses helped make this all possible. Also, additional thanks goes to Merry Springer for her friendship and support and especially for typing this thesis.

Thanks must also be given to all the faculty in the Biology and Chemistry Departments at Central State University. Special thanks must be given to Dr. Thieron Harrison and Dr. William Caire at C. S. U. for their enthusiasm and encouragement during the past many years.

Much thanks must be given to my major advisor, Dr. Ronald J. Tyrl, for his support, patience, encouragement, suggestions, and enthusiasm during the long course of this study.

Most of all, special love and thanks goes to my family, especially my parents, Esther and Ralph Edin, whose love and support developed in me an interest in biology and botany and helped me to complete this degree.

CHAPTER I

INTRODUCTION

The common names smartweed and knotweed were appropriately coined for members of the genus Polygonum as one has to be intelligently aware of the minute separations between species within this genus that have caused many problems for taxonomists in classification and identification. Six closely related species of the section Persicaria--Polygonum pensylvanicum L., P. bicornis Raf., P. longistylum Small, P. omissum Greene, P. mexicanum Small, and P. mississippiense Stanford--constitute one complex within the genus. It is commonly referred to as the P. pensylvanicum complex. Depending on taxonomic interpretation, as many as six or as few as one species have been recognized. Table 1 illustrates these differences in taxonomic opinion. As can be seen, there is a difference in generic circumscription--Small and Correll and Johnston recognized the section Persicaria at the generic level. There is also a difference in the number of taxa recognized, varying from one to four. When an author recognizes bicornis, longistylum is not recognized and vice-versa. Also, it should be noted that P. pensylvanicum is always included in each treatment. Worthy of special note are Small's treatments. Small revised his 1913 treatment twenty years later in 1933 and omitted Persicaria mississippiense but included Persicaria mexicanum. He had described P. mexicanum in 1892, but did not include it in his 1913 treatment. In

recognizing only one species, Dalci (1972) based his decision on the results of his biosystematic study. Mitchell (1980) also classified all members of the complex in one species, Polygonum pensylvanicum. His treatment appeared in a checklist of names for North America; supporting evidence was not presented.

These problems in taxonomic interpretation are due to the tremendous overlap in morphological features among members of the complex as well as distributional and ecological overlaps. Found in moist or wet, disturbed habitats and in flower from late May to November, all taxa are herbaceous annuals or perennials with alternate simple leaves having ocrea. Usually pink flowers of five perianth segments are arranged in condensed racemes. Each flower has six to eight stamens, two styles, and produces a lenticular achene. Plants of the taxa differ most in overall size, style arrangement, stamen arrangement, and fruit characteristics. Moisture differences may be correlated with these morphological differences (Turesson, 1901; Massart, 1902; Nieuwland, 1911; Stanford, 1925; and Mitchell, 1968).

The objective of this research was to determine the relationships among the taxa of this complex by means of detailed morphological examinations and observations of habitat and distribution. It was hoped that through such detailed studies differences and similarities could be determined and a meaningful classification of these taxa developed. Additional limited studies of the cytology, reproductive biology, and pollination ecology of the taxa were made to complement the morphological and ecological investigations.

CHAPTER II

LITERATURE REVIEW

Classification and Nomenclature

Polygonum comprises approximately 200 species and is a member of the Polygonaceae, commonly referred to as the buckwheat, knotweed, or smartweed family. The genus was described by Linnaeus in Species Plantarum (1753).

The genus is often divided into sections. For example, in Gray's Manual of Botany (Fernald, 1950) there are six sections: Avicularia, Bistorta, Persicaria, Echinocaulon, Tiniaria, and Aconogonon. Other authors have elevated the sections to generic rank. Small (1913) and Rydberg (1932) treated the species of polygonums as representing several genera of which Persicaria is one. Correll and Johnston (1970) also split them into several genera. Small treated them both ways, positioning them within sections of Polygonum in his 1892 treatment and as several genera in his 1913 treatment.

The species investigated in this study are traditionally classified in the section Persicaria due to their close morphological similarities. Features of this section include: spike-like racemes, four to six perianth segments, six to eight stamens, two or three styles or cleft styles, and a lenticular or trigonous achene. Steyermark (1963), however, placed P. pensylvanicum and P. bincorne in the section Avicularia. No explanation for this different interpretation was given.

The name Persicaria presents a nomenclatural problem in itself. It is uncertain who first used the name at the generic level. Linnaeus (1753) referred to the subdivisions of Polygonum and used Persicaria. According to Farr et al. (1979) Miller used Persicaria as a genus name in his 1754 Gardener's and Botanist's Dictionary. The 1754 edition was not available to determine whether Miller used Persicaria as a genus name. However, a review of the 1807 edition revealed that Miller was definitely using Persicaria as a sectional name. This confusion is indicated in several taxonomic works. In this work, Polygonum sensu lato is used. Persicaria is treated as a section of Polygonum.

Descriptions of Taxa

Polygonum pensylvanicum

Polygonum pensylvanicum was described by Linnaeus in 1753. Although the specific epithet appears to be misspelled, it is written as Linnaeus first wrote it, possessing one n rather than two as might be expected. As Fernald (1917) noted, Linnaeus and his contemporaries were following the accepted spelling of their day. Maps of the 18th century generally show the spelling "pensylvania."

Linnaeus in Species Plantarum described P. pensylvanicum as having flowers arranged in spikes, each flower mounted on a pedicel and possessing eight stamens. The leaves were described as lanceolate, acuminate, and scabrous, and the ocrea as truncate. The peduncles were described as hispid. The habitat of the plant was given as Pennsylvania. One of the more detailed descriptions of this species was given by Britton and Brown in 1896. Their description included the same information given above and also mentioned the annual habit, the

presence of glands on the peduncles and pedicels, and plant heights to three feet. Plants were said to have dark pink to rose-colored, five-parted flowers with eight or fewer stamens and a two cleft style. A lenticular, smooth, shining achene was also described. Their treatment was the first to mention a stamen number of less than eight. Small (1913) in his Flora of Southeastern United States gave a similar description. In "Ferns and Flowering Plants of Nantucket," Bicknell (1909) compared an erect form similar to that of Britton and Brown to another form, a small prostrate plant with a dark mark on the leaves, dense spikes, and large fruits.

In other descriptions of P. pensylvanicum, similar observations were made. Gray's Manual (Fernald, 1950) described the variation in leaf shape (lanceolate, elliptic, or oval), the variation in pubescence (slightly glandular and hispid to abundantly glandular and sparsely hispid), and the variation in habit (depressed to erect). Fernald specifically noted that the species is highly variable. He further stated that the stamens and styles are usually included, that the flowers are mostly cleistogamaous, and that the stamens possess considerable inviable pollen. Correll and Johnston (1970) noted that plants usually had greenish stems and that the styles and stamens were of similar length and produced in white to pinkish flowers, 3.1-4.2 mm long.

Polygonum pensylvanicum, the most broadly distributed species of those covered in this study, is found throughout the eastern two-thirds of the United States and Canada. Munz and Keck (1959) list P. pensylvanicum as occurring in California and indicate that it is newly

introduced there. Correll and Johnston (1970) state that P. pensylvanicum is found throughout North America.

Infraspecific taxa of Polygonum pensylvanicum have been described. In 1917 Fernald recognized three varieties--var. genuinum, var. laevigatum, and var. nesophilum. Farwell in 1924 described another variety, viridialbum, and Stanford yet another variety, durum, in 1925. Myers (1942) introduced the variety eglandulosum, while Norton one year later (1943) described var. rosaeflorum. Also three forms of P. pensylvanicum have been used--var. laevigatum f. albineum by Farwell in 1923, var. laevigatum f. pallescens by Stanford in 1925, and f. albinum by Fernald in 1945 (a variety was not cited). Species also have been reduced to varietal status within P. pensylvanicum, e.g., P. Oneillii Brenckle which was reduced by Hulten in 1968. These varieties differ in their habit, amount of pubescence, coloration, and distribution. P. pensylvanicum var. genuinum, found from Mississippi eastward, is believed to have been the form considered by Linnaeus when he described P. pensylvanicum. The variety found from New Brunswick to Colorado is laevigatum and is considered the most common.

The varieties of P. pensylvanicum are based on many of the slight differences previously mentioned. Variety genuinum is described as having leaves that are copiously strigose beneath and often above, ocreae that are eciliate to ciliate, and achenes that are 2.2-2.8 mm wide (Fernald, 1917). Variety laevigatum has leaves which are glabrous, ocrea that are eciliate, and achenes of 2.5-3.5 mm wide (Fernald, 1917). The third variety, nesophilum, described by Fernald in 1917 has stems that are depressed, leaves that are elliptic to oval rather than lanceolate, and peduncles which are very short, unlike the other two

varieties. Variety eglandulosum, described by Myers in 1942, is similar to genuinum but lacks pubescence of any kind which is most atypical of the species. As the epithet implies, variety rosaeflorum is distinguished by the rose color of the flowers. This variety, described by Norton in 1942, also has strigose leaves and large achenes some 3.5-4.0 mm long. Also differing in floral color is variety viridialbum (Farwell, 1923). The flowers of this variety are greenish-white and the peduncles are densely glandular. All of these varieties are known from locations in the northeastern United States. Variety durum, type location in Florida, was described as having appressed hairs on the peduncles, lacking glands, and possessing six rather than eight stamens.

Two of the three forms of P. pensylvanicum are of the variety laevigatum. Forma albineum Farwell (1923) of var. laevigatum has white flowers, as does forma albinum Fernald (1945). Fernald does not indicate a variety, but there appear to be no differences in descriptions between the two forms albineum and albinum. The third form, forma pallescens, is also within variety laevigatum and has glands that lack the usual red pigment found in the variety.

Polygonum bincorne Raf. and

Polygonum longistylum Small

Polygonum bincorne was described by Rafinesque in 1817. He described it as a species having plants from four to five feet in height with purplish stems and rose-colored flowers. Populations were said to be found growing in swamps, moist grounds, and along rivers, and are visited by bees as their "flowers smell like honey" (Rafinesque, 1817).

The styles were described as exserted and the stamens included with the plants flowering from August to December.

P. longistylum was described by Small in 1894 as an annual or perennial with erect stems 3-6 dm in height. The leaves were described as lanceolate (narrow to ovate-lanceolate). The stamen number was given as varying from six to eight and described as included while the styles, two in number, were described as being exserted. The achene, black in color and dull or shining, was said to be slightly gibbous. Small made no reference to Rafinesque's P. bicorne but stated that P. longistylum resembled both P. pensylvanicum and P. mexicanum in morphology and geography. Small noted that P. longistylum differed in the long style, small, dull achene, and long-petioled, lanceolate leaves.

As Nieuwland (1914) pointed out, the only difference between Rafinesque's description of P. bicorne and Small's description of P. longistylum is in the size of the plants. General distribution--the deep South--is the same for both taxa. Also noted was that these two taxa were the only American members of the section Persicaria to have exserted styles.

Other descriptions of P. bicorne and P. longistylum are similar. Characteristics mentioned for both include glandular abaxial leaf surfaces (Fernald, 1950) and pale pink flowers with the perianth measuring 2.0-2.5 mm in the long-styled form and 3.0 mm in the short-styled form (Stanford, 1925). The achene has been described as umbonate on one side (Waterfall, 1972) or convex on both sides (Steyermark, 1963). Fernald (1950), Steyermark (1963), and Correll and Johnston (1970) all noted the two forms of the flowers--exserted long styles and included short stamens, or included short styles and exserted

long stamens. Stanford (1925) reported that the first form was more fertile, while Fernald (1950) stated the opposite.

P. longistylum var. omissum has glands on the stems as well as on the peduncle. Only the long-styled form was described.

P. bicorne is distributed over a broad area in the central United States. Correll and Johnston (1970) cite it as occurring in California.

P. longistylum is described from the central United States. Most descriptions give the distributions of these two species as midwestern and central United States, in particular the south central United States. P. longistylum var. omissum's distribution is given as more westward than other varieties of this species.

Nieuwland (1914) stated that P. longistylum must be considered a nomenclatural synonym of P. bicorne as "...the locality in both cases of publication is the same." Shinners (1957) agreed with Nieuwland that the taxa were conspecific, a position followed by taxonomists today. Shinners believed that early American botanists ignored Rafinesque's work because of prejudice and ignorance as they believed he did not look at specimens of the plants when writing his descriptions. Shinners stated that this was not true. The name P. longistylum persists today due to its use in older manuals such as Gray's. Examination of specimens in this investigation indicates that the binomial P. longistylum is indeed a nomenclatural synonym of P. bicorne, hence P. bicorne will be used hereafter.

Polygonum omissum Greene

P. omissum was described by Greene in 1903 as a species with short, erect plants one to two feet tall having glabrous, short leaves. The

deep pink flowers have exserted styles and produce black, shiny achenes. The fruits are described as having one flat and one convex surface. Greene noted that plants of this species had previously been considered to be P. pensylvanicum. A few years later in 1925 Stanford reduced the species to a variety of P. longistylum. P. omissum is described as occurring from Colorado southward.

Polygonum mexicanum Small

In 1892, Small described P. mexicanum noting its similarity to P. pensylvanicum. He described a five-parted, light rose-colored calyx in which were found six to eight stamens and a long, two-parted style. The plants were described as three to four feet in height, having linear, lanceolate leaves, and possessing glands on the peduncles and pedicels. The achene was said to be dull, ovate, and lenticular. Stanford's description (1925) of the species included both included and exserted style forms. He noted that the short-styled forms were less fertile and the exserted forms more common.

The major distribution of P. mexicanum is in Mexico with possible occurrences in Louisiana and Texas. Munz and Keck (1959) also cite it in California, although they list it as a synonym of P. pensylvanicum.

Polygonum mississippiense Stanford

In 1925 Stanford described simultaneously P. mississippiense and a variety of it. He described P. mississippiense as a species with perennial erect plants having narrow, lanceolate leaves. The flowers were described as heterostylous containing six or seven stamens. The fruit is dull black and convex on both sides. The variety interius is

described as having glandular peduncles unlike peduncles of the type specimen which had appressed hairs lacking glands. Distributions, according to Stanford, are the same for both P. mexicanum and P. mississipiensis--from Mississippi to Texas and south to Mexico. Stanford does note that many plants described north of Mexico as P. mexicanum are in fact P. mississipiensis. Plants of the variety interius were collected in Oklahoma.

Recent Interpretations of This Complex

Recognizing only one species, Dalci (1972) in his biosystematic study reduced Polygonum bincorne to a subspecies of P. pensylvanicum. In his work "The Taxonomy of the Section Persicaria (Tourn.) L. in the Genus Polygonum in the United States East of the Rocky Mountains" he described two subspecies of P. pensylvanicum--subsp. pensylvanicum and subsp. bincorne. On the basis of field and greenhouse studies he positioned P. pensylvanicum var. durum within subspecies pensylvanicum. Within subspecies bincorne he placed P. longistylum, P. omissum, P. pensylvanicum var. laevigatum, and P. pensylvanicum forma albinum.

Mitchell, who has published several papers on Polygonum, grouped all of the members of the complex into one species in his 1980 treatment of the genus in A Synonymized Checklist of the Vascular Flora of the United States, Canada, Greenland, Vol. II: The Biota of North America. He presumably based his conclusions on Dalci's study.

Previous Biosystematic Studies

The descriptions presented above illustrate the close similarities in morphology of the members of the Polygonum pensylvanicum complex and

taxonomists have commented repeatedly on these similarities. Although comments are many, biosystematic research which might resolve the problems is limited.

Dalci (1972) conducted limited hybridization experiments and morphological studies on P. pensylvanicum and P. bicornis. Attributing differences in morphology between the two taxa to genetic variation and low levels of outcrossing, Dalci reduced P. bicornis to a subspecies of P. pensylvanicum.

Cytological information is also sparse: chromosome numbers of only one native and five introduced species of the section Persicaria had been reported by 1978 according to McDonald (1978). He obtained chromosome counts of $2n=20$ or 40 for four additional species (P. setaceum, P. hirsutum, P. opelousanum, and P. hydropiperoides). Love and Love (1982) reported several new counts for members of the section, including the first count for P. pensylvanicum, $2n=22$. Prior to this study no count had been made of P. bicornis or other members of the complex. The base numbers of chromosomes for Polygonum are 10, 11, and 17 (Darlington and Wylie, 1955).

A few pollination studies or observations have been made on some species (Robertson, 1928; Dalci, 1972). Doida (1968) studied pollen in the genus and noted that the number of grains per pollen-sac varies from 4 to 8, 16, 32, 64, 128, or 256. Germination studies of the achenes of P. pensylvanicum have been conducted and problems in germination discovered (Ransom, 1935; Everson, 1949; Timson, 1965).

CHAPTER III

METHODS AND MATERIALS

Introduction

Initial field observations of plants identified as Polygonum bicorne in Payne County, Oklahoma, were made in the fall of 1980. Fruits were collected for germination studies. No preliminary field observations were made of P. pensylvanicum. The major divisions of the research embodied in this thesis include field studies, greenhouse studies, and an examination of herbarium specimens. The last was the most extensive part of this research.

Field Studies

Field studies were begun during the summer of 1981 and were conducted also during the summers of 1982 and 1983. Populations of Polygonum were located in Oklahoma, Texas, Kansas, and Arkansas via an examination of herbarium labels and many of the sites were then visited. Additional populations were also located. Major study sites are shown in Figure 1 and detailed descriptions given in Table II.

As populations were discovered, the plants were identified as either P. pensylvanicum or P. bicorne based on the distinguishing characters of style length and achene shape. Features of the habitat, habit of the plants, vegetative and floral morphology of the plants, and phenology were observed. Floral observations included the spatial

relationship of the essential organs, perianth opening and closing times, time of anther dehiscence, floral color, and fruit set. Other observations included those of insect visitors and putative pollinators as well as associated species.

When available, fruit and floral buds were collected for later germination and cytological studies. Floral buds were fixed in the field in 95% ethyl alcohol and glacial acetic acid (3:1 ratio) and later preserved in 70% ethyl alcohol until use (McClintock, 1929). At three locations, bagging and pollen transfer techniques were employed in studies of the reproductive system.

At each study site three or four plants were dug and transplanted into pots for further study. In 1981 collected plants were taken to the University of Oklahoma Biological Station on Lake Texoma, while plants collected in 1982 were transported to greenhouses at Oklahoma State University. Also, at each site three or four flowering specimens were collected and field-pressed for later morphological study.

Greenhouse Studies

Plants collected at each study site were transported to the OSU greenhouses where the growth, habit, and reproductive characters of each could be examined closely.

Floral buds were collected at various times during the day from each plant and preserved for later pollen and cytological examinations.

Daily observations were made of the times of flower opening and closing as well as times of flower dehiscence. Leaf and plant size, numbers of flowers per inflorescence, floral color, and fruit set were also observed.

Crossing studies were conducted by collecting pollen with a fine bristled paint brush and transferring the grains to the stigma. Flowers receiving pollen were emasculated before anther dehiscence. Crosses were made between flowers of the same plant, between flowers of different floral forms of the same species, and between flowers of different species.

Root tips were collected from the potted plants for cytological study. Collection was facilitated by exposed root tips as the roots grew out of the pots. The roots were fixed in the same manner as the floral buds.

Cytological Studies

Root tips and floral buds, collected as described, were squashed and stained using the aceto-carmine technique (McClintock, 1929). Phase-contrast microscopy was used to examine the karyotypes and meiotic behavior. Observations of pollen grains were also made with phase-contrast microscopy.

Studies of Herbarium Specimens

As noted in the preceding chapter, the species of the P. pensylvanicum complex occur throughout most of the United States as well as parts of Canada and Mexico. Herbarium specimens of each species were examined. The specimens were selected to represent the total distributional range. The physiographic divisions of North America were used as a means of subdividing the area to insure adequate sampling (Hunt, 1967; Fig. 2). Using this method of study, specimens from a wide range of environmental conditions could be examined and the variation

exhibited by each species described and understood. Two thousand, two hundred fifty-eight specimens were borrowed from the following herbaria: Missouri Botanical Garden (MO), U. S. Herbarium (US), Southern Methodist University (SMU), University of Nebraska (UN), Gray Herbarium (GRA), New York Botanical Garden (NY), University of Kansas (KU), and University of Oklahoma (OKL). In addition, specimens at Oklahoma State University (OKLA) were used.

The herbarium specimens were sorted according to physiographic regions. Samples were then drawn randomly. Care was taken to represent the entire distributional range within each. The number of specimens examined for each region are given in Figure 2. The longitude and latitude of each specimen were determined. The states and provinces from which herbarium specimens were examined are presented in Figure 3.

In the morphological studies, three hundred seventy-seven specimens were examined. Each specimen was measured or scored for 23 characters--sixteen quantitative and seven qualitative characters (Table III). Additionally, twenty-seven specimens which initially had been identified as P. mexicanum, P. mississippiense, and P. omissum were scored for six characters subsequently determined to be the most discriminating. Univariate and multivariate analyses were conducted on these data using an IBM computer and the Statistical Analysis System (SAS) of Helwig and Council (1979). The analyses included F statistics, Duncan's Multiple Range Test, MANOVA (Multivariate Analyses of Variance), Step-wise Discriminant Functions Analyses, and Principal Component Analyses.

CHAPTER IV

RESULTS AND DISCUSSION

Distribution

On the basis of the evidence presented in the following paragraphs, two species, Polygonum pensylvanicum L. and P. bicornе Raf., are recognized. The binomial P. longistylum Small is considered a nomenclatural synonym of P. bicornе. P. omissum, P. mississippiense, and P. mexicanum are considered conspecific with P. bicornе. To facilitate presentation and comprehension of the data, all comments will focus on P. pensylvanicum and P. bicornе unless specifically noted otherwise.

Initial field and greenhouse observations were crucial in understanding the patterns of morphological variation and thus will be presented first, followed by the analyses of morphology.

Field Observations

The habitat most often given for these species includes semi-aquatic conditions. They are found in waste places where the soil is not well drained. Rivers, ponds, creeks, roadside ditches, irrigation ditches, and low-lying agricultural fields are the major sites of population occurrence.

There are several factors that contribute to the difficulty in locating populations. Moisture availability often regulates the

abundance and period of growth of the plants. The species occur in low areas in disturbed habitats which are often flooded by heavy spring and early summer rains. If flooded, their growth begins much later. On the other hand, if temperatures are high and little or no rain has fallen, germination and growth are limited, if they occur at all.

While along creeks and rivers flooding is a problem, in the other major habitats--roadside ditches and edges of plowed fields--mowing and plowing are the most frequently encountered difficulties.

Another major factor that made populations difficult to locate is the appearance of aggressive weedy species which tend to take over areas once flourishing with Polygonum. Upon returning to several of the localities where populations of the P. pensylvanicum complex were studied initially, it was discovered that the plants were no longer there. The sites had been invaded by such plants as Helianthus annuus, Rhus glabra, Rumex crispus, and Lythrum lanceolatum.

There appear to be differences in the habitats of P. bicornis and P. pensylvanicum with the former occurring in open areas and the latter being located in rockier, less open sites. P. bicornis was found in areas with little canopy such as creek beds, ponds, and plowed fields. The soil usually had a high clay or high sand content. When present P. bicornis usually occurred in abundance, often dominating the area. Species associated with populations of P. bicornis included Solanum elaeagnifolium, Sorghum halepense, Echinochloa crus-galli, Chenopodium sp., and Bromus japonicus. In the field plants of P. bicornis were tall (20-120 cm) and erect.

P. pensylvanicum was found most often along creeks with some canopy. In open areas, it was found around ponds and in roadside

sites, plants did not appear to dominate the area and rarely occurred in abundance. The major species associated with P. pensylvanicum often were other polygonums--P. lapathifolium, P. persicaria, P. hydropiperoides. Other species included those previously mentioned for P. bicorne as well as Rhus radicans, Coreopsis tinctoria, Lythrum lanceolatum, and Sambucus canadensis. The growth form of P. pensylvanicum in the field was short (20-100 cm) and decumbent.

Greenhouse Observations of

Vegetative Morphology

One of the purposes of bringing individual plants of each species into the greenhouse was to observe and compare their morphology and growth in the same environment. Differences in vegetative morphology noticed in the field were supported by the observations made in the greenhouse.

Differences in the heights of greenhouse populations are presented in Table IV. Plants of P. bicorne were tall and erect in the greenhouse. Plants of P. pensylvanicum were much shorter and more decumbent than those in the field. Most floras (Correll and Johnston, 1970; Fernald, 1950) give similar heights (1-20 dm) for both species.

Although pubescence has been used to separate varieties and even species (Small, 1892; Stanford, 1925), the pubescence of the leaves, stems, and peduncles was observed to vary. There appeared to be no consistency among plants of a population in the amount of pubescence. Kubetin and Schaal (1979) reported that plants of P. pensylvanicum further from water exhibited heavier pubescence and leaf spots. They

TABLE IV
AVERAGE HEIGHT OF GREENHOUSE POPULATIONS OF
P. BICORNE RAF. AND P. PENSYLVANICUM L.

Species	Population Number	Number of Plants	Average Height (m)
<u>P. bicornе</u>	99	5	1.50
	101	13	1.15
	108	8	1.78
	109	9	1.62
	110	11	1.37

	147	18	0.63
	148	13	0.58
	150	3	0.84

suggested that the individuals of the populations were genetically similar and that differences were due to phenotypic plasticity.

P. bicine has narrow, lanceolate leaves (Fig. 4), while P. pensylvanicum has much broader, lanceolate leaves. This was observed in the field and also in the greenhouse. The differences in the size of leaves of these species indicated that leaf size might be a major vegetative character that could be used to separate the species. The leaf spots mentioned by Kubitn and Schaal (1979) were found on some plants.

Stem coloration has often been used to distinguish species of Polygonum. Plants of P. pensylvanicum usually exhibited green stems, while those of P. bicine ranged from green to more often red.

Other vegetative characters were similar and of little use in separating the species when floral features were not available.

Reproductive Biology and Phenology

Floral features have been used most often to separate the species of the complex (Stanford, 1925b). The flowers of all individuals were typically polygonaceous. All had five, free perianth segments. Those of P. bicine were almost always bright pink, while the flowers of P. pensylvanicum ranged from white to dark pink or reddish-pink. In one population of P. pensylvanicum all colors were seen; normally, plants of each population were very similar in color. Plants flowered from June through November. P. bicine consistently had eight stamens, while P. pensylvanicum had six, seven, or eight. Both species possessed a two-cleft style and nectaries around the ovary at the base of the stamens.

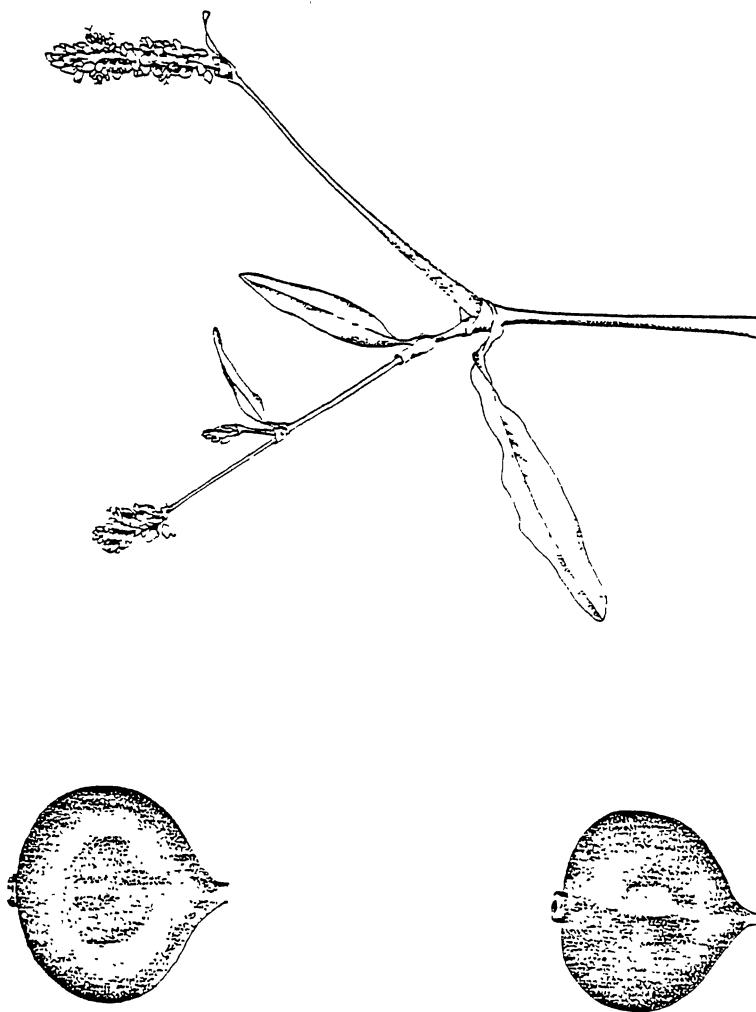

Figure 4. *Polygonum bicornis*: Illustration of Achenes
and Portions of Shoots

Heterostyly¹, a genetically controlled floral polymorphism in which a species produces flowers which differ in style and stamen lengths and are self-incompatible, is characteristic of P. bicorne. In all field observations of P. bicorne the long-styled and the short-styled morphs were present in each population. The ratio of forms was essentially 50:50 which is in agreement with Ornduff's observation (1971) that, in general, both forms are found in equal numbers in plants exhibiting heterostyly. The long-styled, or pin-form, had styles exserted beyond the perianth and possessed short, included stamens. The short-styled, or thrum-form, possessed long, exserted stamens and short, included styles. The flower forms of P. bicorne are illustrated in Figure 5.

In contrast to the heterostylos condition of P. bicorne, all individuals of P. pensylvanicum had styles and stamens that were of nearly equal length and not exserted beyond the perianth (Fig. 5). P. pensylvanicum is described as cleistogamous and self-compatible (Dalcí, 1972; Stanford, 1925; Meehan, 1889); open flowers, however, were observed in this study.

In the field, fruit set appeared high for both species although percentages are not available because of problems in maintaining field populations; however, this was not the case in the greenhouse studies

¹An excellent explanation of heterostyly is given by Ganders (1979). He states that taxa have two forms only; rarely does an intermediate form exist. Also, rarely are heterostylos individuals self-compatible. Pin plants are homozygous recessive (ss) and thrums are heterozygous (Ss). This explains the equal numbers of the two forms in a population. According to Gander, the heterostyly mechanism "...increases disassortive pollination and results in assymmetric pollen flow in populations." Pollination, not just self-compatibility, must be considered in understanding the mechanism of heterostyly.

Figure 5. Flowers of P. pensylvanicum (top) and
P. bicorne (left, pin-flower;
right, thrum-flower), Illustrating
Differences in Floral Morphology

(Table V). Plants of P. pensylvanicum had high fruit set, while plants of P. bicorne had low fruit set. Such results are expected due to the self-compatibility of P. pensylvanicum and the self-incompatible flowers of P. bicorne. The formation of fruits by the plants of P. bicorne is likely due to the fact that insects were not completely excluded from the building. Fruit set may also be due to accidental cross-pollination that may have occurred as the plants were moved from one greenhouse to another and the close proximity of the plants to each other.

Observations of the pollination ecology of P. bicorne and P. pensylvanicum were made in the field; most were similar to those reported by Robinson (1928). Bumblebees (Bombus spp.) were frequent visitors, along with wasps, other bees, and flies. Monarch butterflies were observed on P. bicorne, and a few other moths and butterflies were also observed. Only the bees, wasps, and flies appeared to be gathering nectar. Flowers were visited in early to late morning by most insects. Robinson (1928) listed 98 insects visiting P. pensylvanicum. Insects observed by him and in this study included: Bombus separatus, Bombus americanorum, Halictus parallelus (Hymenoptera), Eristalis aenus and Eristalis tenax (Diptera), and Chrysophanus, Eurymus, and Vanessa atalanta (Lepidoptera). Robinson observed only one member of the order Coleoptera on P. pensylvanicum. The species observed was Chauliognathus pennsylvanicus, the goldenrod soldier beetle. In the studies of this research two members of the Coleoptera were observed on plants of P. pensylvanicum. These observations included the goldenrod soldier beetle as well as the long snout beetle (Curculionidae). The larva of the long snout beetle was observed making its home in the stem of the plant. Neither of these beetles was observed on P. bicorne.

	101	14	73	--	8	0-37
	108	11	100	16	34	1-160
	109	15	89	--	45	1-223
	110	19	106	19	47	2-208
	115	16	85	15	13	0-51
	133	22	149	25	38	0-202
<u>P. Pensylvanicum</u>	145	3	130	25	1297	1854-3402
	147	18	127	32	2461	994-3942
	148	9	70	25	1599	540-3864
	150	3	128	31	2663	2054-3456

Flowers of both species opened between 08:30 and 11:00 hours C.D.T. in the field as well as in the greenhouse. They closed between 16:30 and 18:00 hours C.D.T. Flowers of P. bicorne opened fully with the perianth tips extending outward from the center of the flower, while flowers of P. pensylvanicum opened only about three-fourths of the way with the perianth tips pointed inward toward the center of the flower. The flowers of both species remained opened one or two days. Flowers of P. bicorne typically remained opened longer. The degree and length of flower opening is correlated with the reproductive mode: cross-pollination versus self-pollination.

Determination of anther dehiscence was difficult. The anthers of P. pensylvanicum generally dehisced prior to flower opening; occasionally dehiscence occurred as the flower opened or after. This observation supports reports of cleistogamy in this species. P. bicorne was found to have anthers dehiscing at almost any time, but most often 30-90 minutes after flower opening. The number of pollen grains per locule differed between the two species. P. pensylvanicum has fewer than 19 per locule, while P. bicorne had more than 32 per locule. Attempts to determine the time of stigma receptivity were not successful.

Achene morphology was different in each species. The achene of P. bicorne was convex or umbonate (Fig. 4) while that of P. pensylvanicum was larger and flat.

Cytology

Mitotic chromosome counts from root tips of plants grown in the greenhouse or from germinating achenes could not be obtained. The small size of the roots prevented successful squashing and resolution of

cytological configurations. In future studies, it may be advantageous to grow the germinating seedlings in a liquid medium before maceration to increase the size of the roots.

Collecting material for meiotic chromosome studies was also difficult. The appropriate stage for collection is the very young floral bud that is still subtended by the ocreolae. The entire bud was squashed due to its tiny structure. Suguira (1936) also reported the same difficulty in obtaining counts for Polygonum.

P. bicornis was observed to have a chromosome number of $2n=56$. Counts were obtained from one bud. In the slide eleven pollen mother cells were observed. Three cells had 28 bivalents (Fig. 6), two cells had 26 bivalents, and one cell had 27 bivalents. In the other five cells counts were not obtained. This would indicate a somatic chromosome number of 56, 52, or 54. Meiotic configurations analysed were in diakinesis.

The chromosome number of P. pensylvanicum is reported to be $2n=22$ (Love and Love, 1982). Additional counts of P. pensylvanicum were not obtained in this study. Base numbers for the genus are ten, eleven, and seventeen (Darlington and Wylie, 1955). The somatic chromosome number of 56 for P. bicornis suggests a base of seven or fourteen. Additional cytological work is needed.

Morphology and Statistical Analysis

In order to understand the morphological variability of the members of the complex, extensive studies of herbarium specimens from most of the United States, Canada, and Mexico were conducted. Many herbarium

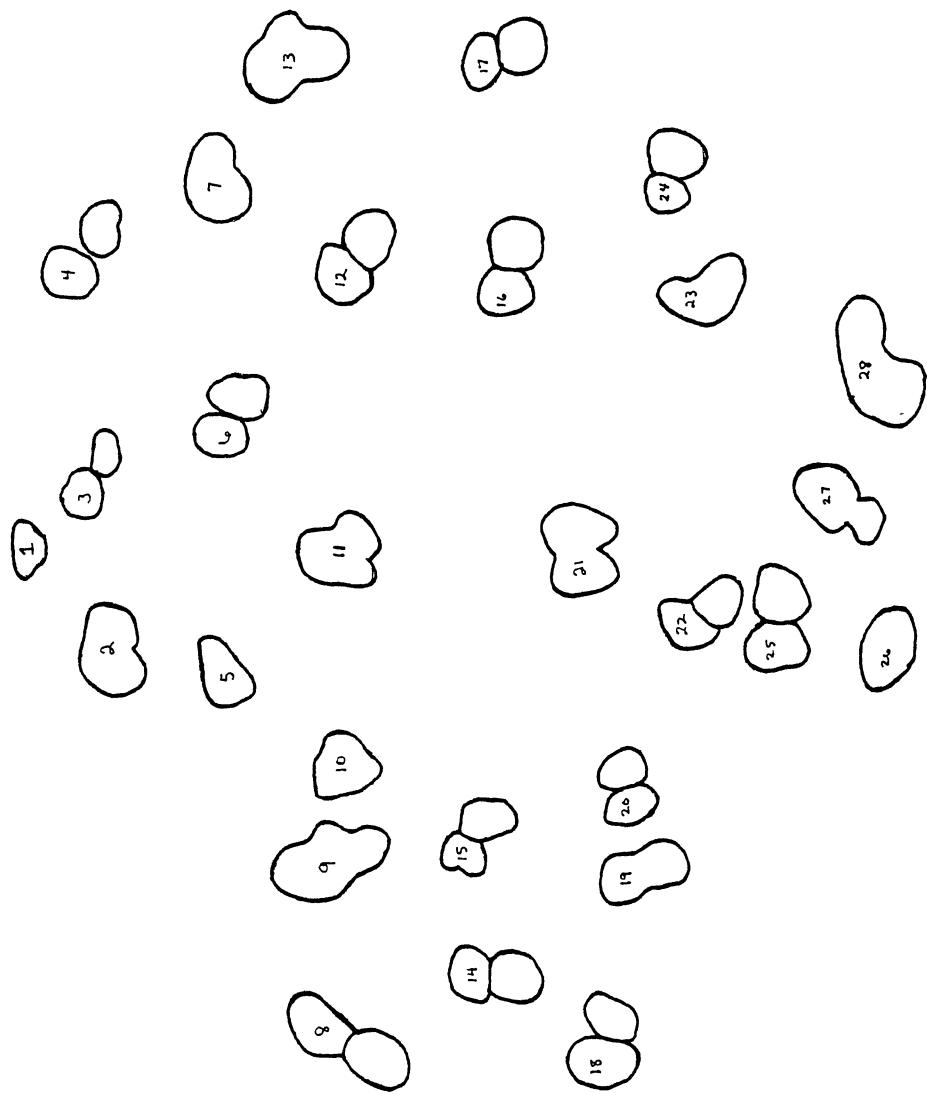

Figure 6. Drawing of Meiotic Prophase I Chromosomes of
P. bicorne (n=28)

specimens of P. lapathifolium and P. persicaria were misidentified as members of this complex. It was noted that several specimens used in Dalci's 1972 study of the complex were misidentified which leads one to believe that his decision to recognize one species P. pensylvanicum had been made in haste.

Univariate analyses were conducted in order to ascertain the variability of each character throughout the range of the species. Variation for each character was large (Table VI). Intra-regional variation is presented in Table VII.

Duncan's Multiple Range Test is a mean separation procedure and was used to compare long and short-styled forms of P. bicornis and P. pensylvanicum (Table VI). Of the twenty-three characters, eleven separated the two species. Of these characters, blade width and length, stamen length, style length, and achene length, width, and shape had been used in separating these species in the field during this study. Pedicel length also separates the taxa. The pedicels are shorter in P. pensylvanicum. Pedicels have been shown to be of differing lengths depending on reproductive mechanisms (Hickmann, 1982).

Multivariate analyses were used to better understand an individual character's relationship to all other features. Stepwise Discriminant Analysis is a multivariate analysis technique to determine the most discriminating characters. It also permits a comparison of the positioning of individual plants by statistical means with that of the taxonomist. Table VIII lists the most discriminating characters for these species. Table IX shows that when using all characters only five specimens were repositioned. Plants initially identified as P. pensylvanicum were identified in the discriminant analysis as P. bicornis.

Inflorescence length	4.829	0.0085

(short style). Stamen and style lengths were then removed from the analysis as they are used as the major characters for identification. When this was done (Table X), the species still could be separated. Often all characters are not needed to identify a plant to species, so only the eight most discriminating characters were used in the analysis (Table XI). Again, P. bicorne and P. pensylvanicum were clearly separated. The last of the discriminant analyses was with the six most discriminating variables; stamen and style lengths were excluded (Table XII). The two species were separated, but the two forms of P. bicorne were not.

Other multivariate analyses conducted included four MANOVA Tests (Multivariate Analysis of Variance). These procedures use least squares means to determine differences between groups when all variables are considered together. All four MANOVA Tests showed significant differences between groups (Table XIII). Morphometric data for each species from physiographic regions 4C, 4G, 5, 6, and 7 were subjected to MANOVA Tests to determine whether differences among regions existed. There were significant differences among regions for P. pensylvanicum and for P. bicorne (Table XIV). This further indicates the wide range of variability for each species. It was determined from additional MANOVA Tests that, despite the high variability of each species, the difference between P. bicorne and P. pensylvanicum within a region was still significant, further supporting the separation of these taxa.

Principal components analysis is another multivariate analysis technique useful in understanding patterns of variation and taxon relationships. This procedure creates from the observed set of characters a new set of characters that are uncorrelated. The first

principal components account for most of the variation and are often the only ones used in comparisons. Figure 7 illustrates the plot of the first two principal components in the analysis based on 23 characters. There is separation although some overlap is apparent. Two distinct groups corresponding to P. pensylvanicum and P. bicorne are illustrated in the plot of principal components (Fig. 8) based on the analysis of only the eight most discriminating characters. When stamen and style lengths are included in the analysis, subgroups of P. bicorne are visible (Fig. 8), but when they are excluded from the analysis the subgroups are indistinguishable (Fig. 9).

Twenty-seven additional specimens initially identified as P. mexicanum, P. mississipense, and P. omissum were added to the data set and analyses conducted. Figure 10 illustrates the plot of the first two principal components for the six most discriminating characters for all specimens scored. As is apparent, specimens initially identified as P. mexicanum, P. mississipense, and P. omissum appear throughout the plot and are intermingled with specimens of both P. pensylvanicum and P. bicorne. These statistical analyses support the field and greenhouse observations. All observations and analyses indicate taxonomic recognition of two species, P. pensylvanicum and P. bicorne.

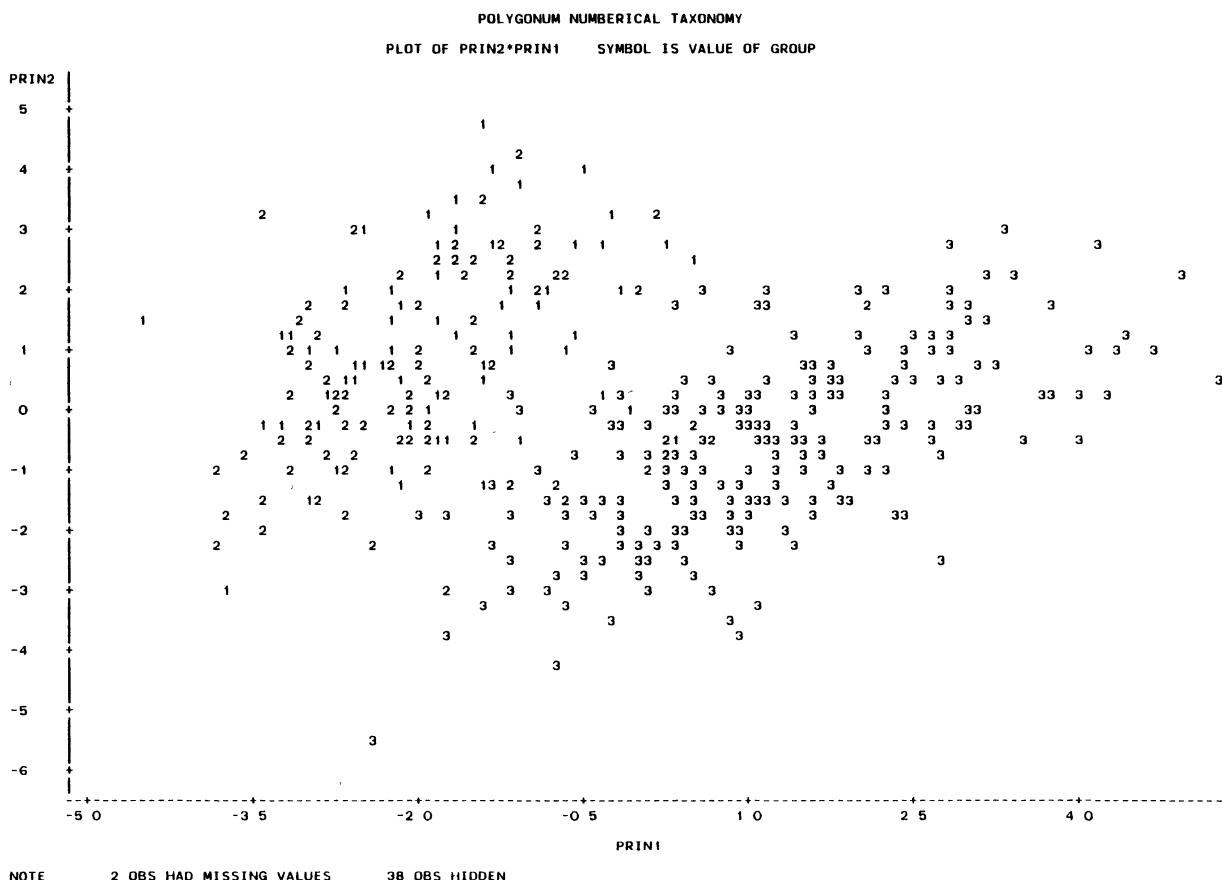

Figure 7. Plot of Principal Components 1 and 2 (23 characters) of Group 1 (P. bicorne--long style), Group 2 (P. bicorne--short style), and Group 3 (P. pensylvanicum)

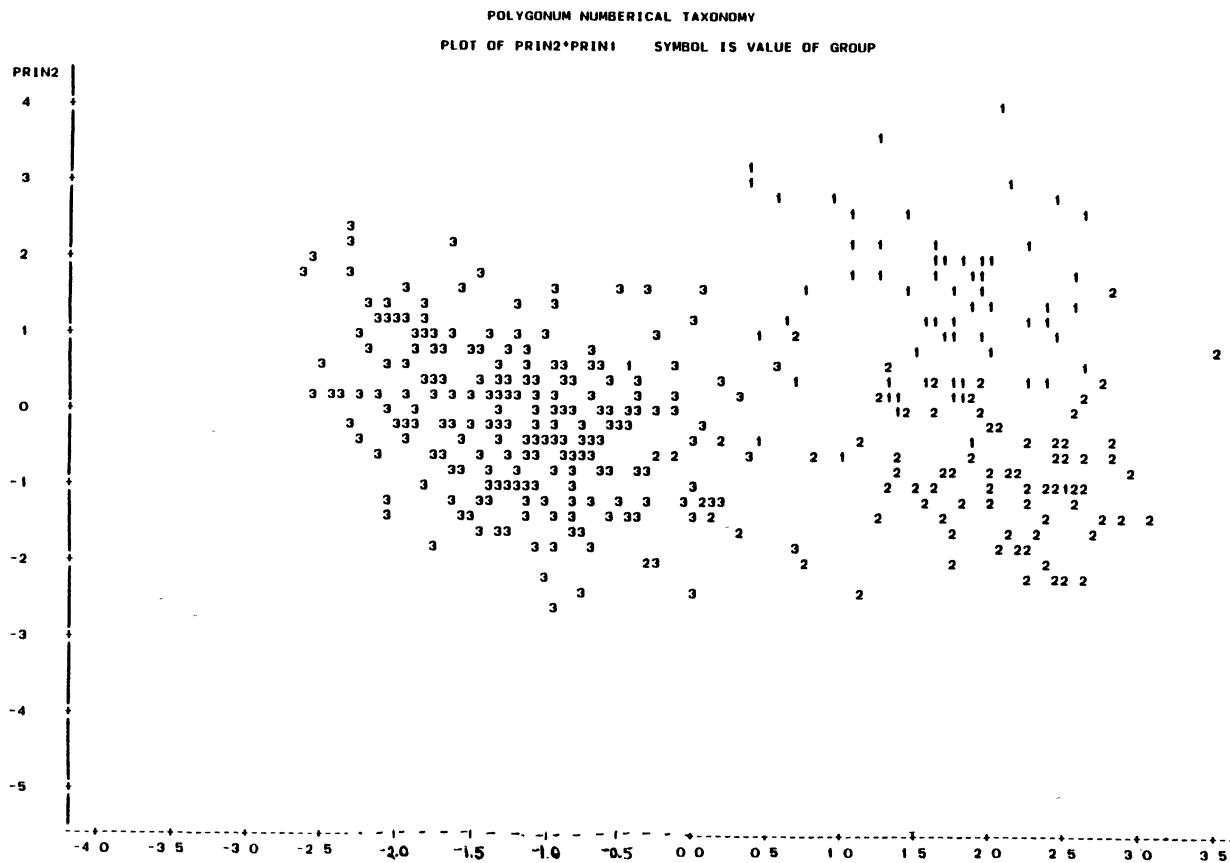

Figure 8. Plot of Principal Components 1 and 2 (8 most discriminating characters) of Group 1 (P. bicorne--long style), Group 2 (P. bicorne--short style), and Group 3 (P. pensylvanicum)

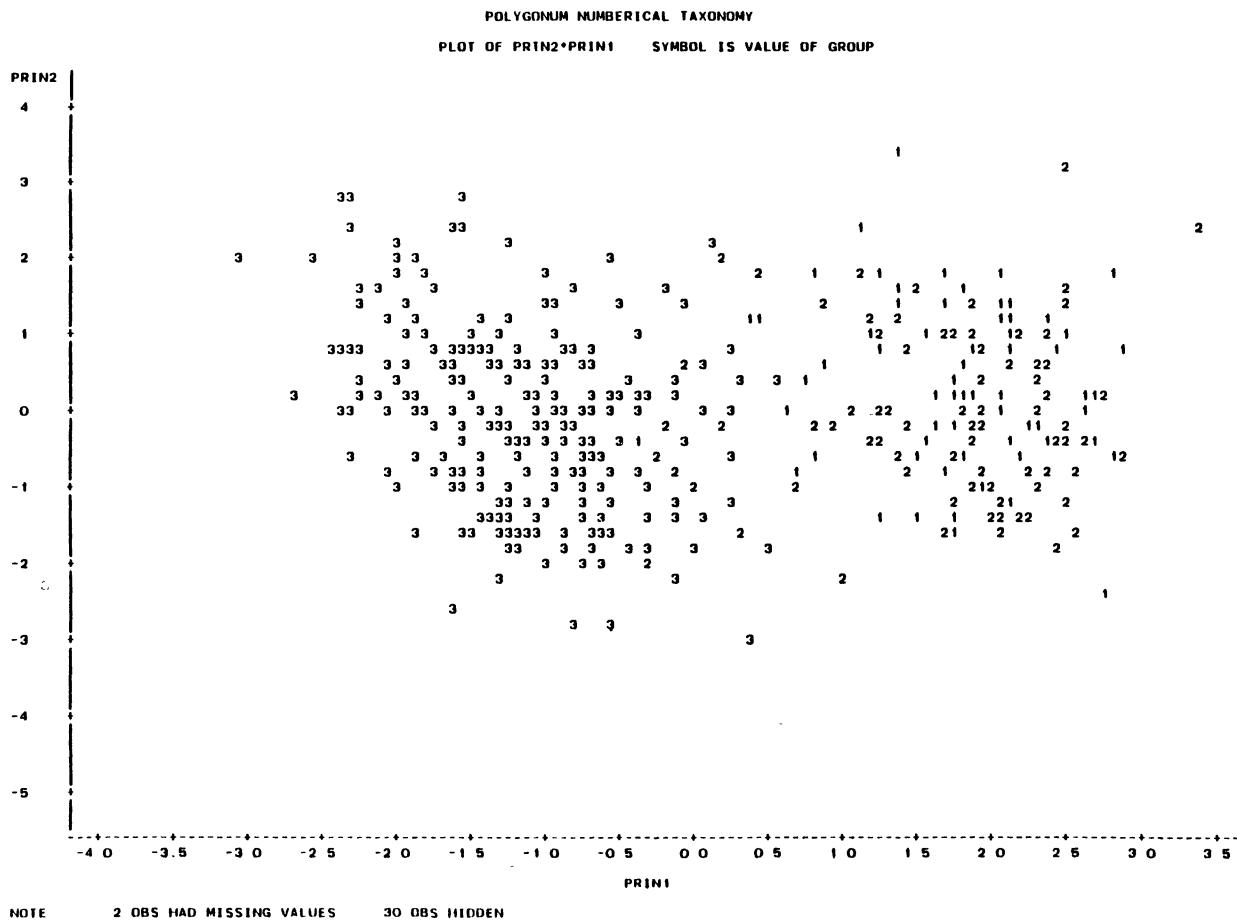

Figure 9. Plot of Principal Components 1 and 2 (6 characters, excluding stamen and style lengths) of Group 1 (*P. bicorne*--long style), Group 2 (*P. bicorne*--short style), and Group 3 (*P. pensylvanicum*)

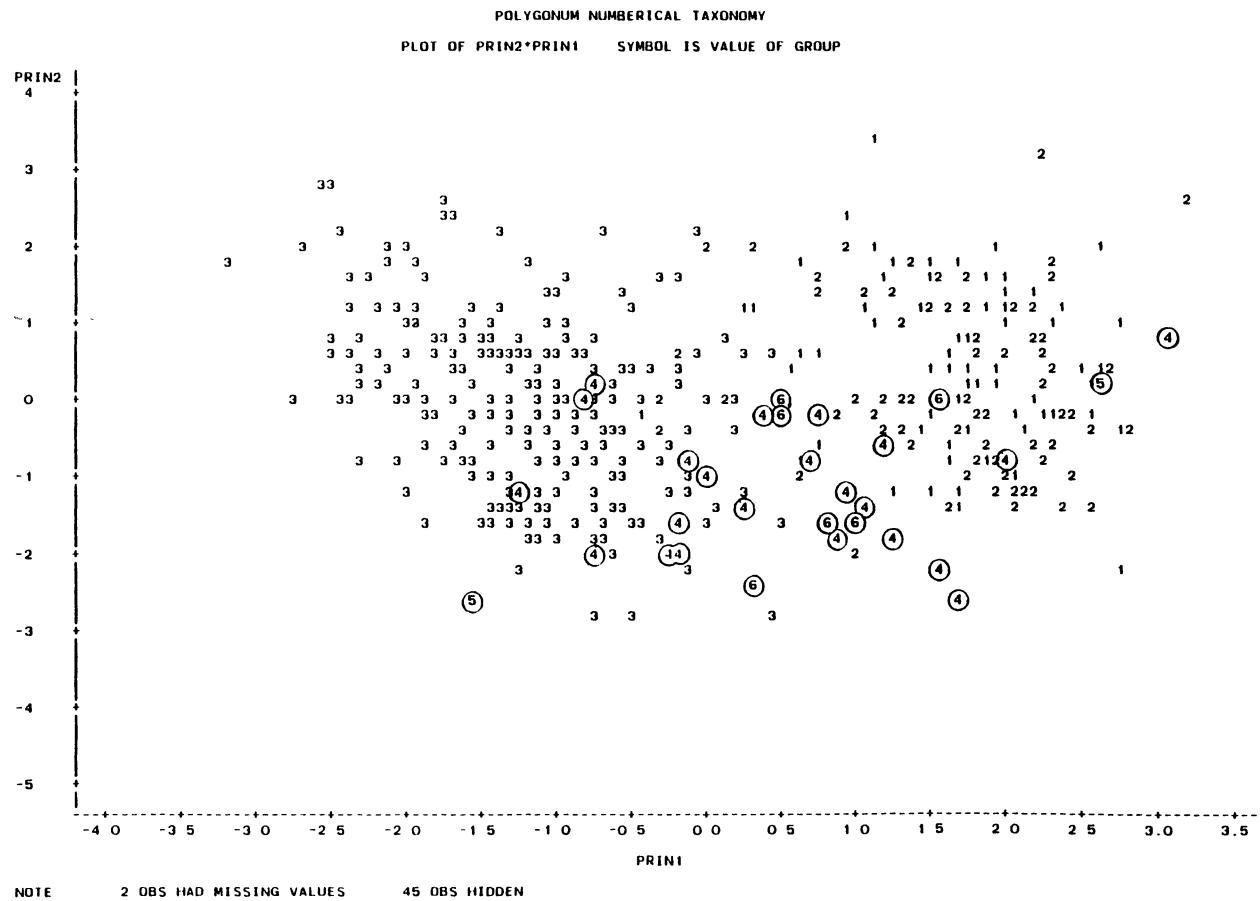

Figure 10. Plot of Principal Components 1 and 2 (6 characters, excluding stamen and style lengths) of Group 1 (P. bicorne--long style), Group 2 (P. bicorne--short style), Group 3 (P. pensylvanicum), Group 4 (P. mexicanum), Group 5 (P. omissum), and Group 6 (P. mississippiense)

CHAPTER V

SUMMARY

On the basis of the data gathered in this study, it is believed that taxonomic recognition of two species, P. pensylvanicum and P. bicornе, is warranted. P. bicornе Raf. is maintained. P. longistylum Small is considered a nomenclatural synonym. P. omissum Greene, P. mexicanum Small, and P. mississippiense Stanford are also considered conspecific. P. mexicanum may possibly be recognized as a variety of P. bicornе because of its smaller, duller achenes and distribution in the south-central United States and Mexico; additional study is required before a taxonomic decision is made.

P. pensylvanicum L. is maintained as a separate species. It is distinct from P. bicone in morphology and reproductive biology. The present study did not directly address varieties which have been proposed in P. pensylvanicum; however, based on subjective impressions, the investigator does not feel that these categories are warranted because of continuous variation and environmental effects. Keys and descriptions are given below.

Key to Species

Flowers heterostylous; stamens or styles exserted; stamens 8; achenes convex, 1.5–2.8 mm in width Polygonum bincorne

POLYGONUM PENNSYLVANICUM L.

Linnaeus. Species Plantarum. London. 1753.

P. pensylvanicum var. genuinum Fernald. Rhodora 19:70–73. 1917.

P. pensylvanicum var. laevigatum Fernald. Rhodora 19:70–73. 1917.

P. pensylvanicum var. durum Stanford. Rhodora 27:173–184. 1925.

P. pensylvanicum var. laevigatum f. pallescens Stanford. Rhodora 27:173–184. 1925.

P. pensylvanicum var. eglandulosum Myers. Castanea 7:74–75. 1942.

P. pensylvanicum var. rosaeflorum Norton. Castanea 7:74–75. 1943.

P. pensylvanicum f. albinum Fernald. Rhodora 47:93–142. 1945.

P. pensylvanicum var. Oneillii (Brenckle) Hulten. Flora of Alaska and Neighboring Territories: A Manual of the Vascular Plants. 1968.

Polygonum pensylvanicum L. Annual; herbaceous; height 1–12 dm; stem decumbent to erect, usually green; pubescence variable, penduncles with or without glands, leaves broadly lanceolate, 15–202 mm long and 4 mm wide; petiole length variable, 2–36 mm long; ocrea papery and entire, 3–24 mm long; internode length variable, 8–105 mm long; peduncle length variable, 7–81 mm long; inflorescences terminal, 14–62 mm long and 6–18 mm wide; racemes spicate; flowers subtended by ocreolae 2–5 mm long; pedicels 1–4 mm long; flowers

subtended by ocreolae 2-5 mm long; pedicels 1-4 mm long; flowers cleistogamous and homostylous; perianth in one series, 5-parted, white to reddish-pink, 2-4 mm long and 1-3 mm wide, opening about three-quarters; stamens often 6 (sometimes 7 or 8), 1-5 mm long; style one, two-cleft, 1-3 mm long; achenes lenticular, broad, flat, dull to shiny, dark brown, 2-4 mm long and 1-3 mm wide.

Eastern United States and forested mountain regions of the western United States. Creek, river, and pond margins with sandy or rocky soils, occasionally roadside ditches. Flowering period May to December.

POLYGONUM BICORNE RAF.Rafinesque. Flora Ludoviciana. 1817.P. mexicanum Small. Bulletin Torrey Botanical Club 14:351-370.

VITA

Irene Catherine Edin

Candidate for the Degree of

Master of Science

Thesis: A BIOSYSTEMATIC STUDY OF THE POLYGONUM PENNSYLVANICUM
COMPLEX (POLYGONACEAE)

Major Field: Botany

Biographical:

Personal Data: Born in Oklahoma City, Oklahoma, March 2, 1958, the daughter of Ralph J. and Esther R. Edin.

Education: Graduate of Northeast High School, Okla. City, OK, May 1976; received Bachelor of Science degree in Biology from Central State University, Edmond, OK, May 1980; completed the requirements for Master of Science degree at Oklahoma State University, May, 1986.

Professional Experience: Undergraduate Research Participant (NSF Grant), University of Oklahoma, Norman, OK, June - Aug. 1978; Lab Assistant, Central State University, Edmond, OK, Sept. 1978 - May 1980; Research Assistant, Central State University, Edmond, OK, July 1979 - April 1980; Graduate Teaching Assistant, University of Oklahoma Biological Station, Kingston, OK, June - Aug. 1980 and June - Aug. 1981; Graduate Teaching Assistant, Oklahoma State University, Stillwater, OK, Aug. 1980 - May 1981, Aug. 1981 - Dec. 1981, Aug. 1982 - May 1983; Student Teaching Experience, Stillwater High School, Stillwater, OK, March 1983 - May 1983; Secondary Science Teacher, Perkins-Tryon High School, Perkins, OK, Aug. 1983 - present.

Professional Organizations: The Oklahoma Academy of Science, the American Society of Plant Taxonomists, Southwestern Association of Naturalists, Oklahoma Education Association, National Education Association, and the National Science Teachers Association.
