ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. Lawrence G. Morrill for his guidance, suggestions, support, and assistance throughout this study. Special appreciation is given to Dr. Lester Reed, Dr. David Weeks, and Dr. Dale Weibel for their advice and helpful suggestions. Special gratitude is expressed Dr. David Weeks for his guidance and assistance in the process of computer programs and data analysis.

Recognition and appreciation is given to my wife for her understanding, patience, and help throughout the study.

Finally, the author wishes to express his gratitude to my very close friends Mr. Shirmohamad Ardalan and Mr. Bahram Raoufi for their help in field work and for all those good times we had together.

CHAPTER I

INTRNDUCTION

The world stock of protein is decreasing, and the oilseeds protein are expected to play an important role in supplementing protein in the future. Since peanuts are already an acceptable edible oilseed crop their protein may be a source th prevent deficiencies of the future.

Balkcom (3) estimated a market for vegetable protein products of \$92 million in 1972, to be worth \$1.5 billion by 1980. Peanuts as human food occupy a unique position in the United States. In contrast with other countries where they are considered principally as a source of edible oil, in the United States only a fraction of the crop is pressdd for oil and most of this comes from the lower quality nuts.

One of the principle objectives in a research program concerned with the nutrition of peanuts is obtaining high yields with good kernel development by reducing the number of unfilled ovarian cavities and producing larger nuts. Thus, information on phosphorus (P) and calcium (Ca) effects on peanut quality, as well as the physiological processes which take place when peanut fruit develop are seen to be of vital importance.

It has been found that soils with considerable

amorphous iron (Fe) and aluminum (Al) oxides-hydroxides prevent good recovery from P fertilization. The high Ca level of some soils has been implicated in reversion and retention reactions showing poor P fertilization dfficiency. Foth (15) indicates that the earth's crust contains about 1/10 percent phosphorus, and is frequently too low to support the maximum crop production.

The major problem in P uptake from soil by plants is the low solubility of many P compounds. This results in very low concentrations of available P in the soil solution at any time. An understanding of P reactions in soils and the peanut physiological responses are seen as methods to increase peanut production and minimize P fertilizer losses and hence, costs.

Some farmers are applying high rates of gypsum $(CaSO_4 \cdot 2H_2O)$ to the pegging zone of peanuts to furnish Ca needs and to improve soil conditions for harvesting and thereby increasing percent sound mature kernel (% SMK). On the other hand, by applying gypsum every yeas, they will build up the level of Ca in the soil wiich may result in a decrease in awailability of P and a reduction in total marketable product.

The objective of this study was to find out if a supplementary foliar application of P will compensate for a reduction of available P in the soil when gypsum is applied, due to phosphate reversion reactions or increase peanut. yields by interaction with soil Ca and P.

CHAPTER II

LITERATURE REVIEW

The unique way in which the peanut obtains nutrients from the soil, and the need for some elements in large amounts, such as Ca, has resulted in confusion over the years. The grower must consider the peanut as a plant with two active root systems: one, feeding deep in the soil, and the other being the short stubby root hairs formed near the tip of the peg as it penetrates uhe soil and coming from the shell of the developiog nut. This second root system seems to be more selective in nutrient uptake with large demand for calcium. The main root system functions as does the root system of most other plants, except it is generally more active deep in the soil (36, 39).

> Calcium and Phosphorus Requirements for Peanuts and Their Effect on Quality and Yield

The peanut plant is unique compared to other field crops. Its fruiting behavior and morphology vary greatly from other crops and probably accounts for the differences in how the peanut plant utilizes applied nutrients. Peanuts are good P feeders and appear to obtain adequate P when the

soil levels are less than optimum for many other crops. However, the most consistent yield increases from plant nutrients has been from P application (1). Phosphorus gives the peanuts a faster start. This helps in getting ahead of weeds as well as increasing the productive growth period for better maturity of nuts. P deficiency symptoms are not as definite in peanuts as with some other crops, but the entire plant is usually stunted.

Daughty and Cox (13) observed that Ca is vital io peanut production. Uniquely, Ca must be applied to two zones of absorption (the pegging and root zones). Adequate Ca reduces the occurrence of "pops" and unsound kernels. The pegging zone should contain more Ca than potassium (K). If K level is greater than Ca the yield will be decreased (44).

According to past research, gypsum (CaSO₄·2H₂O) is the best source of Ca for peanuts. Peanuts are frequently grown in sandy soil or sandy loams with low cation exchange capacity. The peanut plant has a high demand for Ca in the pegging zooe at the time the nuts are setting and developing (22, 26). Research has indicated that gypsum will improve soil structure by promoting flocculation and granulation and will speed water penetration in puddled or dispersed and heavy soils, reducing crusting and sealing at the surface. Soils supplied with adequate Ca produce fruit with an increase in percent sound mature kernels (%SMK) (10, 33, 38).

Vanry and Vandiest (42) explained that P is involved in many plant functions. It serves as an energy storehouse for plant metabolism through the adenosine diphosphate-adenosine triphosphate (ADP-ATP) transformations. Phosphorus is a constituent of some proteins and is necessary for the growth of plants, as well.

Many investigators (4, 18, 34) explain that the deficiency of P may prevent other nutrients, such as nitrogen (N), from being absorbed by plants. Availability of P in the soil depends on the stage of soil weathering, pH, organic matter, soil texture, percentage of CaCO₃, and percentage of hydrated iron and aluminum oxides.

Archer (2) and Barrow (5, 6) studied the P reactions in soil and found that they are more complex than those of any other nutrient element. Both organic and inorganic forms of P can be found in soils and they are important to plants as sources of P. Under acid conditions, where the clay surface and the exchange complex contains active Al and Fe, these elements react with phosphate to form P compounds of low solubility. Phosphorus reversion in alkaline and calcareous soils is due to the formation of slightly soluble Ca-P complexs. When soils are high in CaCO₃ P may form $CO_3^{=}-PO_4^{-}$ complexs rather than simple $CO_3(PO_4)_2$ (5, 6).

Taylor and Ellis (40) pointed out that the mechanism of P adsorption on soil and homogeneous soil mineral surfaces is not clearly defined in the literature. However, it is

generally agreed that for the clay and sesquioxide mineral surfaces, phosphate ions replace exposed OH groups and/or other adsorbed anions (40). Whether the bonds between the phosphate ions and the Fe⁺³ and Al⁺³ atoms at colloid surfaces are ionic, covalent, or coordinate-covalent is not agreed upon.

Foliar Application of Nutrient Elements

Foliar spraying is an alternative to soil application for introduction of nutrients to plants. Because fertilizer salts can be taken up rapidly and metabolized by leaves, it is possible to fertilize crops specifically at periods of high nutrient demand during rapid vegetative growth or fruit development (19). Foliar application may be used when there is some difficulty or limitation in soil availability of plant nutrients. Garcia and Hanway (19) provided experimental and theoretical support for the idea that lateseason foliar spray of fertilizers can increase yield in legumes. Their results are summarized in Tables I and II.

Malakondaiah and Rajeswararao (27) conducted an experiment on foliar application of P on peanuts under salt stress and observed that foliar nutrition induced significant increases in yield compared to the addition of fertilizer to the soil, especially under saline conditions. They observed that when P was sprayed on the leaves, there was an increase in accumulation of P in both control andsalinized plants. They concluded that the depression in

TABLE I

uptake through the root system, either due to abnormal pH or due to physiological unavailability, had been overcome by facilitating absorption through the leaves. Accumulation of salts or sodium (Na⁺) causes a decrease in the uptake of potassium (K⁺) and Ca⁺⁺ supply of P by foliar spray resulted in partial improvement of the depressing effect (27).

Greenway (20), and Neumann (30) studied foliar application of nutrients and pointed out that the plants can utilize water soluble nutrients through their foliage via foliar sprays. The nutrients enter the leaf cells by penetrating the cuticle of the leaf or through stomata. When problems of soil fixation or excessive leaching of nutrients exist, foliar application may well constitute the most effective means of fertilizer application.

Calvert and Smith (11) and Calvert (12) explained the use of foliar application of major nutrient elements in horticulture. They mentioned that considerable research had been focused on foliar application of fertilizer nutrients in horticulture and it is an established practice in many areas of the world. The foliar spraying of micronutrients like boron, copper, magnesium, and zinc to control the deficiencies of these elements is a common practice for citrus and other agronomic crops in California and Florida. More recently, studies have been conducted on the foliar spraying of major elements, N, P, and K. Calvert (12) mentioned that the use of a foliar spray of a major, fertilizer element is not usually a substitute for ground

fertilization, but may be a very significant supplement to it. He said, foliar spraying of fertilizer elements can increase the level of major fertilizer elements for short, critical periods.

Calvert (12) explained there are a number of reasons for occasional, and sometimes, extended short supply of major elements in plants, which lead to the need for supplemental spraying of horticultural and agronomic crops with N, P, or K. It may be practical to spray to overcome the interferences brought about by other fertilizer ions in the soil. For example, the adsorption of potassium from soil is often strongly influenced by soil conditions, such as high concentrations of Ca and Na, or other cations which reduce K uptake. Calvert found a foliar spray of KNO₃ was more effective in raising the K content of leaves than the equivalent amounts of K applied in the ground for citrus.

Gorde and Kibe (21) studied the effects of foliar and soil application of P fertilizer on Chinese mung beans (<u>Phaseolus aures</u>). They found significant increases of N, P, and K in P treated plants as compared with a control.

Bouma (7), and Patra (32) studied foliar application of P and N as urea polyphosphate and found that the total dry matter of the plant increased as compared with the control. Bouma pointed out that foliar feeding of P contributed to the recovery from P deficiency in subterranean clovers, especially when the availability of P applied to the root

zone is not seriously restricted by soil conditions.

Wittwer and Teubner (43) investigated foliar absorption of mineral nutrients on bean plants. They reported that plants deficient in P absorbed foliar applied P more rapidly than those grown in P rich media.

Ohlrogge and Kamprath (31) were able to increase the yield of soybeans in Iowa from 3695 to 5225 kg/ha with foliar sprays. This was the largest yield increase they obtained from several experiments conducted over a two year period and represents the average for two indeterminate varieties. Their spray material was composed of potassium polyphosphate (0-26-25), K_2SO_4 , $(NH_4)_2SO_4$, and urea in the same relative concentrations of N, P, K, and sulfur (S) found in the seed. The amounts of N, P, K, and applied S were 140, 14.5, 42, and 8.4 kg/ha, respectively, based on an expected yield increase of 1800 kg/ha.

Robertson et al. (35), and Nagel et al. (29) in Florida, studied the foliar fertilization of 'Cobb' soybeans to supply nutrients to the pods at a time when uptake from the soil was declining. Sources of materials, times of application, and rates were variables in their study. They did not observe a significant yield increase. They thought the most likely reason for failure to obtain a yield response was due to leaf burn.

Barel and Black (8) studied the suitability of 32 different P compounds for foliar applications by using a new technique in which predetermined quantities of P were applied to a fixed leaf area. They found the most successful compound for corn was ammonium triphosphate, $(NH_4)_{2}H_3P_3O_{10}$, which could be applied at 370 micrograms (ug) of P/cm² of leaf area without causing leaf damage. They found 66% of the applied P was absorbed within 10 days and 78% of the absorbed P was translocated to other tissues. Other compounds used successfully for foliar treatment of corn were ammonium tetrapolyphosphate, $(NH_4)_2H_4P_4O_{13}$, and phosphoryl triade, $(NH_2)_3PO$. Soybeans proved more sensitive than corn to foliar sprays and could, in general, tolerate only two-thirds to three-fourths the quantity (rates) successfully applied to corn. Ammonium tri- and tetrapolyphosphate, $(NH_4)_2H_3P_3O_{10}$ and $(NH_4)_2H_4P_4O_{13}$ could be applied at 220 ug of P/cm² soybean leaf area.

Process of Foliar Penetration and Absorption of Substances

For many years botanists have been looking for the mechanism by which various substances penetrate plant leaves. It has been generalized that any substance which is applied to or sprayed on a leaf surface is absorbed by the trichomes or glandular hairs and later excreted into the adjacent epidermal cells. The substance migrates through the chlorophyll-free tissue along the veins, where it finally is absorbed by elements of the vascular bundles (23). Sharma and Vandenborn (38) and Leece and Kenworthy (25) point out that the cuticle is the first barrier to any foreign substance applied to the surface of the leaf. They studied the foliar penetration of herbicides and mention that partial removal of the surface wax with chloroform results in a 1.5 to 4-fold increase in herbicide penetration. The stomata are considered to be another primary pathway of foliar absorption (25, 38).

Dybing and Currier (14) studied foliar penetration by chemicals and found that cuticular penetration, with the exception of ^{32}P -Phosphate was slow. Stomatal penetration of aqueous solutions occurred rapidly if the proper concentration of an efficient surfactant was used. Biswas (9) studied absorption, diffusion and translocation of ^{14}C labeled triazine herbicides in peanut leaves and observed that a surfactant almost always increased herbicide absorption.

Frankie (16) also investigated the mechanisms of foliar penetration of solutions and found that ectodesmata, fine structures in the outerwalls of epidermal cells, were directly related to foliar absorption.

Factors Affecting the Absorption and Translocation of Foliar Spray

Factors which affect absorption and subsequent translocation of the foliar applied phosphorus include: P. concentrations of the spray, leaf surface (upper vs. lower), wetting agent, different P compounds (pH and cation), time, size of area sprayed, age and position of sprayed leaf, and P level of plant (17).

Koontz and Bidduiph (24) tested three methods (leaf vein injection, droplet, and spray application) and suggested for routine use spray application proved superior, and is the method which is best adapted for field use. He also determined effects of pH and associated cations on the absorption and translocation of P. Phosphoric acid (H_3PO_4) and the following three series of P compounds were used: 1. NaH₂PO₄·H₂O, Na₂HPO₄·7H₂O, Na₃PO₄; 2. KH₂PO₄, K₂HPO₄, K₃PO₄ and 3. NH₄H₂PO₄, $(NH_4)_{2}$ HPO₄. The results with the sodium and potassium compounds showed the 10 mM H₃PO₄ solution injured the sprayed leaves and only 4.7% of the applied P was translocated.

Fisher and Walter (17) investigated the effect of different P compounds on absorption and translocation and mentioned that the difference between P absorption from ammonium (NH_4^+) and K salts is small. The inclusion of glycerine in the spray solution increased P absorption over an extended period of time. Glycerine could conceivably increase P absorption because of its moisture conditioning and its spreader properties. There was no increase in P absorption detected by addition of urea or formamide to the spray solutions.

CHAPTER III

METHODS AND MATERIALS

Experiment I

This experiment was conducted at Caddo Research Station at Fort Cobb, Oklahoma. The field plot was initiated in 1964 and gypsum was applied to the plots only in 1965 and 1966 with yield and quality information collected for several years after.

No fertilizer or gypsum was applied in this experiment, only the residual effect was considered. Fourteen treatment combinations as shown in Table III were arranged in 14 plots, 6-91.44 cm rows X 18.29 m long, as a split-plot on strips experiment with four replications. The purpose of the experiment was to investigate the effect of foliar application of P on Spanish peanuts (<u>Arachis hypogea</u>) as a supplementary feeding to prevent any P deficiency which may occur due to P reversion in presence of high Ca levels.

Potassium monobasic phosphate (KH₂PO₄) with the concentration of 0.35 percent P was used as a foliar spray applied to the half of the plots which had received past gypsum treatments, and to one-half the plots which had not received gypsum (28, 41).

Phosphorus spray was applied as a foliar spray with a small backpack hand sprayer, twice during the growing season (July 24, 1981 and August 15, 1981). The two center rows of the peanut plots were harvested and air dried. The yield per acre, % SMK, and total kernel content (TKC) were determined and the data analyzed statistically. The experiment of 1981 was repeated in 1982. Soil samples were taken in 1982 to monitor the levels of N, P, K, Ca, and pH. The major soil of the experiment is of the Cobb soil series--a minimum Reddish Prairie soil (fine-loamy, mixed, thermic, Udic Haplustalfs).

Experiment II

This experiment was performed at Stratford Agronomy Research Station without irrigation in 1981. Twelve treatment combinations, as shown in Table IV, were arranged in 12 plots, 6-91.44 cm rows X 18.29 m long, as a split-plot on strips experiment with four replications. The 12 treatments included three levels of applied P (0, 45, and 90 kg/ha) and four levels of gypsum (0, 336, 672, and 1009 kg/ha). Ground gypsum was applied as a top dressing to half of the plots within the four replications. Foliar P was applied to three rows of the six row plots. Three adjacent rows of each plot were selected randomly for foliar application of P. Therefore, each plot was divided into four subplots for treatments as follows: gypsum, gypsum plus foliar P, foliar P, and check. The foliar treatments

TABLE IV

EXPERIMENTAL TREATMENT IDENTIFICATION

•

were the same for Experiment II as for Experiment I. Peanuts were harvested within each subplot and the data collected for statistical analysis as in Experiment I.

In 1982, the experiment was repeated. A new rate of gypsum (1681 kg/ha) was applied to one fourth of those plots (treatments 1, 2, 3) that did not receive gypsum in 1981. Potassium pyrophosphate ($K_4P_2O_7$) solution with 0.35 percent concentration of P was applied as a new foliar P source to one fourth of each main plot containing treatments 1, 2, and 3 for comparison with KH_2PO_4 . The major soil of the experiment is of the Daugherty series (loamy-mixed, Thermic Arenic Haplustalfs).

Soil samples from all the plots were taken in 1982 to monitor the levels of N, P, K, Ca, and pH. Analyses were made according to Oklahoma State University Soil Testing Lab procedures and the results of the soil analyses for Experiments I and II are presented in the appendix.

The least significant differences (LSD) in this experiment related to the yield, % SMK, and TKC are calculated based on averaged means of foliar vs. not foliar (8 observations) or gypsum vs. not gypsum.

CHAPTER IV

RESULTS AND DISCUSSION

Stratford Experiment

When no P was applied to the soil, foliar P had significant effect on yield and TKC when 336 or 672 kg/ha gypsum was applied to the soil (OSL < 0.05). The yields were increased by as much as 404 kg/ha compared with no gypsum and no foliar spray (Table VI).

Yield of plots receiving foliar P were significantly different regardless of gypsum application rate (OSL < 0.05) (Tables VIII, IX, X). The application rate of 672 kg/ha gypsum gave better yields and equivalent % SMK as 1009 kg/ha gypsum and resulted in a higher TKC (Tables VI and VII). The highest yields were obtained when the combination of foliar P and 672 kg/ha gypsum were used. There was no significant interaction between foliar P and gypsum. The yield results are shown in Tables V through XIII and Figures 1 through 9.

Without applying foliar P yield was depressed when going from 672 kg/ha gypsum to 1009 kg/ha. The yield was increased when going from 336 kg/ha gypsum to 672 kg/ha (Tables VIII, IX, and X). The depressing effect of gypsum

at the highest rate may be related to the effect of P reversion, since foliar P applied increased the yield and TKC significantly.

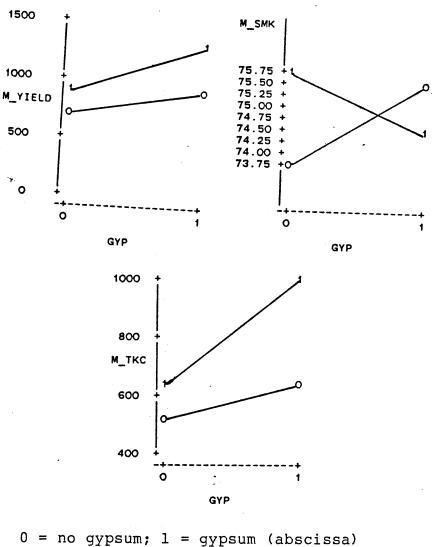

Figure 9. Effects of 1009 kg/ha Gypsum and 90 kg/ha P on Yield, % SMK, and TKC of Spanish Peanuts (Stratford, 1981).

Gypsum and foliar P treatments significantly affected yield and TKC when 90 kg/ha P were applied to the soil (Tables XI, XII, XIII). The combination of gypsum with foliar spray P when 1009 kg/ha gypsum was applied increased the yield by 483 kg/ha compared to gypsum alone (Table XIII). An inference might be drawn that gypsum blocked P uptake.

In 1982 the experiment was repeated. The combination of four levels of gypsum and three levels of phosphorus fertilizer, which make up the 12 treatments, were analyzed in relation to foliar spray P response. The data is presented in Tables XIV through XXII and in Figures 10 through 18.

The variables yield, % SMK, and TKC were significantly affected by foliar P application in some combination of foliar P with soil P fertilization rate and/or gypsum application. Gypsum had a significant effect only on % SMK (Tables XIV and XXII). The combination of gypsum and foliar spray of P treatment was superior in yield, % SMK, and TKC. Interactions between gypsum and foliar P were not significant for yield % SMK, and TKC (Tables XIV, XV, and XVI, also Figures 10, 11, and 12).

Yield response to foliar spray of P was significant but was not to gypsum at 336 kg/ha rate (Tables XIV, XV, XVI). However, the highest yield, % SMK, and TKC were obtained when a combination of gypsum and foliar P were applied (Tables XVII, XVIII, and XIX, also Figures 13, 14, and 15).

Figure 17. Effects of 672 kg/ha Gypsum and 90 kg/ha P on Yield, % SMK, and TKC of Spanish Peanuts (Stratford, 1982).

M = mean.

Effects of 1009 kg/ha Gypsum and 90 kg/ha P on Yield, % SMK, and TKC of Spanish Peanuts (Stratford, 1982). Figure 18.

At the P fertilizer rate of 90 kg/ha, foliar P increased yield significantly except for the gypsum rate of 1009 kg/ha (Table XXII). Percent SMK was not increased significantly by foliar P when gypsum rate was 336 or 672 kg/ha (Tables XX and XXI).

Foliar application of P increased the TKC significantly when P fertilizer rate was 90 kg/ha regardless of gypsum rate (OSL < 0.05) (Tables XX, XXI, and XXII, also Figures 16, 17, and 18).

According to the literature, gypsum will increase % SMK. This is basically confirmed by this study. Gypsum also increased yield at lower rates, at higher rates the yield was decreased regardless of P fertilizer rate.

In 1982 a new rate of gypsum (1681 kg/ha) was applied to 1/4 of the plots which did not receive gypsum in 1981. A new P compound for foliar P (potassium pyrophosphate, $K_4P_2O_7$) was applied to the other 1/4 of these plots to find out if there was a difference between KH_2PO_4 and $K_4P_2O_7$ at P concentration of 0.35 percent as a foliar P source. The combination of gypsum (1681 kg/ha) and foliar P (KH_2PO_4) increased the yield significantly only at 0 level of P fertilizer rate compared to the plot receiving only foliar P (KH_2PO_4) (Table XXIII).

Potassium phosphate (KH_2PO_4) as a foliar P gave better results on the yield and TKC of Spanish peanuts than $K_4P_2O_7$. There was no significant difference between the two P compounds as foliar spray when 90 kg/ha of P was applied to

TABLE XXIII

COMPARISON OF TWO DIFFERENT P COMPOUNDS USED AS FOLIAR SPRAYS (KH2PO4 and K4P2O7) ON YIELD, % SMK, AND TKC OF SPANISH PEANUTS (STRATFORD, 1982)

*1 indicates the corresponding compound has been used as foliar spray with 0.35% concentration of `P.

Fort Cobb Experiment

Foliar spray of P (KH₂PO₄) did not have a significant effect on yield, % SMK, and TKC of Spanish peanuts in 1981. Harsh weather at the time of sprayings, especially rainfall shortly after spraying may be the main cause for the foliar spray being ineffective. Previous gypsum treatment had a significant effect on % SMK, it increased % SMK from 63.23 to 65.35 percent (Tables XXV and XXVI).

LSD		124	0.64	87	

Foliar spray of P significantly affected the yield, % SMK, and TKC of Spanish peanuts at Fort Cobb in 1982. The yield increase due to foliar spray was 409 kg/ha, TKC increased by 334 kg/ha. A benefit to foliar P spray application is clear. Depending on the price of peanuts, the farmer may earn (net) from \$60 to \$110 per acre more by the use of a foliar P spray in combination with gypsum application.

There was no significant effect of residual gypsum on yield, and TKC of Spanish peanuts (OSL = 0.90) after 12 years at Fort Cobb.

Table XXVII shows the effect of foliar application P in relation to residual gypsum application and NPK fertilizer combination. The numbers are mean yield, mean % SMK, and mean TKC averaged over four replications. There were no significant differences between the seven N-P-K combinations in 1981. Different N-P-K combinations significantly affected the % SMk in 1982, the LSD based on 16 observations averaged over foliar and gypsum was 2.6.

*0 indicates no gypsum or foliar application; 1 indicates there is gypsum or foliar spray.

**See Table III in Methods and Materials.

CHAPTER V

SUMMARY AND CONCLUSIONS

Two experiments were conducted at two locations (Fort Cobb and Stratford) to study the benefit of foliar spray P (0.35% solution of KH₂PO₄) in relation with gypsum application and P fertilizer rates on yield, % SMK, TKC of Spanish peanuts.

Four rates of gypsum (0, 336, 672, 1009 kg/ha) were applied in the Stratford experiments; residual effect of gypsum was considered in the Fort Cobb experiments. Two years data (1981, 1982) were collected for statistical analysis.

The following information was obtained from this study.

Stratford Experiment

 Foliar application of P increased yield, % SMK and TKC of Spanish peanuts in many combinations with gypsum and P fertilization rates.

2. Gypsum application increased the % SMK. This result has been reported in the literature.

3. Yield response to gypsum generally increased up to 672 kg/ha, then decreased for the higher rate of gypsum (1009 kg/ha).

 Combination of gypsum (672 kg/ha) and foliar application of P produced the highest yields and TKC.

Fort Cobb Experiment

1. Foliar application of P significantly increased yield, % SMK, and TKC of Spanish peanuts in 1982. There were no significant increases due to foliar spray P for yield, % SMK, and TKC in 1981. Unfavorable weather conditions is speculated as the cause.

 Response of % SMK to residual gypsum was significant only in 1981.

General Conclusions

1. Since the foliar application of P in combination with gypsum application on Spanish peanuts in experimental plots show benefits of up to \$110/acre, trials under farmer field conditions should be run. In addition, detailed analyses of soil levels of P and Ca and plnat content of P and Ca should be made. Undoubtably there are threshold levels of soil P and Ca beyond which foliar P applications will not show increases in net profit. However, many Oklahoma peanut farmers may benefit measurably by use of foliar P application.

2. The continued increase in yield when foliar P is applied to Spanish peanuts grown at higher soil P fertilization rates may lead to an impression that foliar P treatments will increase P uptake from the soil (see Table XXIV). This suggestion should be viewed with caution since no direct measurements of soil P uptake were made. The effect might be the result of a larger leaf surface receiving foliar P in the higher P fertilized plots.
