Received 29 July 2006/Accepted 31 August 2006

The phytopathogenic bacterium *Pseudomonas syringae* pv. glycinea infects soybean plants and causes bacterial blight. In addition to *P. syringae*, the human pathogen *Pseudomonas aeruginosa* and the soil bacterium *Azotobacter vinelandii* produce the exopolysaccharide alginate, a copolymer of D-mannuronic and L-guluronic acids. Alginate production in *P. syringae* has been associated with increased fitness and virulence in planta. Alginate biosynthesis is tightly controlled by proteins encoded by the *algT-muc* regulatory gene cluster in *P. aeruginosa* and *A. vinelandii*. These genes encode the alternative sigma factor AlgT (σ^{22}), its anti-sigma factors MucA and MucB, MucC, a protein with a controversial function that is absent in *P. syringae*, and MucD, a periplasmic serine protease and homolog of HtrA in *Escherichia coli*. We compared an alginate-deficient *algT* mutant of *P. syringae* pv. glycinea with an alginate-producing derivative in which *algT* is intact. The alginate-producing derivative grew significantly slower in vitro growth but showed increased epiphytic fitness and better symptom development in planta. Evaluation of expression levels for *algT*, *mucA*, *mucB*, *mucD*, and *algD*, which encodes an alginate biosynthesis gene, showed that *mucD* transcription is not dependent on AlgT in *P. syringae* in vitro. Promoter mapping using primer extension experiments confirmed this finding. Results of reverse transcription-PCR demonstrated that *algT*, *mucA*, and *mucB* are cotranscribed as an operon in *P. syringae*. Northern blot analysis revealed that *mucD* was expressed as a 1.75-kb monocistronic mRNA in *P. syringae*.

Pseudomonas syringae undergoes diverse host-specific interactions with plants and is subdivided into >50 different pathovars based on host specificity (29). *P. syringae* pv. glycinea PG4180 infects soybean plants (*Glycine max*) and induces bacterial blight disease. The infection process involves epiphytic colonization, entry into the plant apoplast, multiplication within host tissue, and manifestation of disease symptoms (1, 29). Different cellular determinants, e.g., exopolysaccharides (EPS) or toxins, help *P. syringae* to cope with its diverse natural niches, host responses, and environmental conditions (4).

Exopolysaccharides are carbohydrate polymers that are secreted by a wide variety of bacteria and form a loosely associated extracellular slime or remain closely attached to cells as capsules (64). EPS have multiple functions, including water absorption, accumulation of minerals and nutrients, and protection from hydrophobic and toxic macromolecules (14). *P. syringae* produces at least two EPS: (i) levan, a β-(2,6) polyfructan with extensive branching through β-(1,4) linkages; and (ii) alginate, a copolymer of O-acetylated β-(1,4)-linked D-mannuronic acid and its C-5 epimer, L-guluronic acid (25, 28, 38, 49). Previous studies on EPS produced by *P. syringae* indicated that alginate was the major exopolysaccharide produced in planta (17). Alginate production has been associated with increased epiphytic fitness, resistance to desiccation and toxic molecules, the induction of water-soaked lesions, and the colonization and/or dissemination of *P. syringae* in planta (17, 58, 69). A direct correlation between virulence of *P. syringae* and the quantity of alginate produced in planta has been demonstrated (24, 49). Bacterial alginate is produced by *Azotobacter vinelandii* and several species of *Pseudomonas*, where it is widespread in the rRNA homology group I (18, 44).

Alginate biosynthesis has been studied extensively in *Pseudomonas aeruginosa*, where it functions as a major virulence factor in strains infecting the lungs of cystic fibrosis patients (55). Biosynthesis of alginate in *P. syringae* is similar to that established for *P. aeruginosa* (18, 19, 54, 69). Genes required for alginate biosynthesis in *P. aeruginosa* and *P. syringae* are organized in a chromosomal operon (*algD-algA*), with the *algC* biosynthetic gene located at a different position on the chromosome (11, 53, 54, 70). The first gene of the operon, *algD*, encodes GDP-mannose dehydrogenase, whose enzymatic activity is the rate-limiting step in the alginate biosynthetic pathway (63).

An important feature of alginate production by *P. aeruginosa* is that alginate biosynthetic genes are normally silent but are activated at the stage of chronic infection in the cystic fibrotic lung, which results in a mucoid phenotype (40). Although wild-type *P. aeruginosa* strains have the genetic capacity to synthesize alginate, they normally produce only very small amounts of this polymer (2, 37, 56). Similarly, most phytopathogenic strains of *P. syringae*, including PG4180, are normally nonmucoid (35). In *P. aeruginosa* the alginate biosyn-

thetic operon is tightly controlled by several two-component regulatory systems and the alternative sigma factor, AlgT (44, 62). AlgT functions as a global stress response sigma factor that induces a number of other genetic traits in *P. aeruginosa* (21, 22, 60). AlgT (σ^{22}), which is functionally homologous to RpoE (σ^E) from *Escherichia coli*, is encoded by the first gene in a cluster comprising the main switch controlling alginate biosynthesis. AlgT activates its own transcription and that of *algD* in *P. aeruginosa*, *P. syringae*, and *A. vinelandii* (27, 34, 43, 66). The *algT* (*rpoE*) gene cluster is conserved in several other bacteria, including *A. vinelandii*, *Photobacterium*, and *E. coli* (10, 13, 43, 47). Interestingly, the *algT-mucABCD* gene cluster of *P. aeruginosa* and *A. vinelandii* harbors five genes, whereas *P. syringae* lacks *mucC*. In *Photobacterium* and *E. coli*, there are no *mucD* homologs directly associated with the *rpoE* gene cluster (23, 33, 43, 44). Instead, *htrA*, the *E. coli mucD* homolog, maps at a different position in the genome, and transcription of the monocistronic *htrA* mRNA depends on RpoE (51). MucA, MucB, and MucD were shown to act as negative regulators of AlgT in *P. aeruginosa* and *A. vinelandii* (6, 43, 45, 48, 57, 61). MucD belongs to the HtrA family of periplasmic serine proteases, which are effectors of the extreme stress response and degrade improperly folded proteins in the periplasm (6, 51).

In the present study, we investigated the role of *algT* in *P. syringae* pv. glycinea in alginate production and its effect on growth in vitro and in planta. Transcriptional analysis revealed that AlgT activates *mucA*, *mucB*, *algD*, and its own transcription, whereas *mucD* transcription is not dependent on AlgT. Using primer extension experiments, we mapped a separate promoter for *mucD*, thus providing evidence that *mucD* in *P. syringae* pv. glycinea is not cotranscribed with the *algT-muc* operon but instead is transcribed as a monocistronic mRNA.

MATERIALS AND METHODS

Bacterial strains, plasmids, and growth conditions. Bacterial strains and plasmids used in this study are listed in Table 1. *Escherichia coli* and *Pseudomonas aeruginosa* strains were maintained at 37°C on Luria-Bertani medium (59). *Azotobacter vinelandii* was maintained at 28°C on Burk's medium (50). *P. syringae* was maintained at 28°C on mannitol-glutamate (MG) medium (32). For liquid cultures of *P. syringae* incubated at 18 or 28°C, bacteria were grown in Hoitink-Sinden minimal (HSC) medium (52). Bacterial growth was monitored by measuring the optical density at 600 nm (OD_{600}). Antibiotics were added at the following concentrations (in micrograms/milliliter): ampicillin, 50; kanamycin, 25; and tetracycline, 25.

Molecular genetic techniques. Plasmid isolation, restriction enzyme digests, agarose gel electrophoresis, Southern blots, electroporation, PCR, and other routine molecular methods were performed using standard protocols (59). Isolation of plasmid DNA from *P. syringae* was accomplished by the method of Kado and Liu (31). Genomic DNA from *P. syringae* was isolated as described by Ausubel et al. (3).

Cloning and sequencing of the *algT-mucABD* gene cluster of PG4180. A clone containing the *algT-mucABD* gene cluster was identified from a genomic library of PG4180 (28) by Southern hybridization with a 1.1-kb BamHI fragment containing the *mucD* gene. An 8.9-kb SalI fragment, containing the *algT-muc* gene cluster, was subcloned into pBluescript SK(+) (Stratagene, Heidelberg, Germany), yielding plasmid pBlueSK:AXSalgTop, and was sequenced commercially (MWG Biotech, Ebersberg, Germany). Comparative sequence analysis of

PG4180 and PG4180.muc was done using primers alg_seq1, alg_seq2, alg_seq3, and alg_seq4 (Table 2).

Construction of pBBR3-AXSalgTop and pBBR3-AXSalgT. A 5.1-kb fragment containing the *algT-mucABD* gene cluster was amplified by PCR from genomic DNA of PG4180.muc using primers alg-Operon_fwd and alg-Operon_rev (Table 2). The product was digested with XbaI-HindIII and ligated into the broad-host-range vector pBBR1MCS-3 (36), resulting in pBBR3-AXSalgTop. The 5.1-kb PCR product was also digested with XbaI-PmlI, yielding a 1,837-bp fragment, which contained the 988-bp *algT* promoter region, the 579-bp *algT* coding region, and 270 nucleotides (nt) downstream of *algT* (including a truncated *mucA*). This fragment was cloned into pBBR1MCS-3, yielding plasmid pBBR3-AXSalgT. Plasmids were mobilized into *P. syringae* strains by triparental matings (20).

Isolation and quantification of alginate. Bacteria were grown on MG agar at 28°C for 96 h. Cells were washed from the plates and resuspended in 0.9% NaCl. Alginate isolation and quantification were performed as described by May and Chakrabarty (46), and alginic acid from seaweed (*Macrocystis pyrifera*; Sigma Chemical Co., St. Louis, Mo.) was used as a standard. The experiment was repeated twice, and mean values were expressed as the quantity of alginate produced per milligram of protein.

RNA isolation. Bacteria were cultured in HSC medium at 28°C to an OD_{600} of 1.0 (early to mid-exponential growth phase) and harvested by mixing 15 ml of culture with an equal volume of chilled killing buffer (20 mM Tris-HCl [pH 7.5], 20 mM NaN_3). This mixture was then centrifuged at 4°C for 15 min at 3,220 × *g*. Total RNA was isolated from the cell pellets by acid phenol-chloroform extraction as described by Majumdar et al. (41). The RNA concentration was determined by measuring the absorbance at 260 nm (59).

RNA spot blot and Northern blot analyses. For RNA spot blot analysis, aliquots of total RNA (200 ng per spot) were transferred to nylon membranes (Pall, Dreieich, Germany) using the Minifold I Spot-Blot System (Schleicher & Schuell BioScience, Dassel, Germany). For Northern blot analysis, aliquots of total RNA (1.5 μg per lane) and an RNA size standard (0.24- to 9.5-kb RNA ladder; 3 μg per lane; Invitrogen, Karlsruhe, Germany) were separated by denaturing glyoxal RNA agarose gel electrophoresis as described by Burnett (9) and transferred to nylon membrane as described by Ingelbrecht et al. (30). Successful transfer of the RNA was verified by reversible staining of the membrane with methylene blue (26). Transcript sizes were estimated by comparison with an RNA size standard and with 16S rRNA and 23S rRNA bands.

RNA hybridization probes were generated by in vitro transcription of PCR products. Gene-specific primers (Table 2) were used to amplify PCR products from genomic DNA of *P. syringae*, *P. aeruginosa*, or *A. vinelandii*. The reverse primers carried a T7 promoter sequence at their 5′ ends. Digoxigenin-labeled RNA probes were synthesized using the Strip-EZ RNA Probe Synthesis and Removal kit (Ambion Europe, Cambridgeshire, United Kingdom) and digoxigenin-11-UTP (Roche Diagnostics, Mannheim, Germany), yielding hybridization probes of the following sizes internal to the structural genes: for *algT*, 536 nucleotides (nt) (algT_fwd, algT_revT7); *mucA*, 431 nt (mucA_fwd, mucA_revT7); *mucB*, 501 nt (mucB_fwd, mucB_revT7); *mucD*, 511 nt (mucD_fwd, mucD_revT7); *algD*, 641 nt (algD_fwd, algD_revT7); $mucD_{A.vinelandii}$, 426 nt (mucD_fwd_deg, mucD_revT7_deg); $mucD_{P.aeruginosa}$, 325 nt (mucD_fwd, mucD_revT7_deg). Hybridization, washing steps, antibody reactions, and signal detection and quantification using an FLA-3000 phosphoimager (Raytest, Straubenhardt, Germany) were done according to standard procedures (59) and the manufacturer's recommendations.

RT-PCR fragment analysis. Total RNA was treated with RNase-free DNase I (Ambion Europe, Cambridgeshire, United Kingdom). A phenol-chloroform/isoamyl alcohol (25:24:1) and successive chloroform/isoamyl alcohol (24:1) extraction step was used to remove DNase I. The RNA was recovered from the aqueous phase by adding ammonium acetate (final concentration of 0.5 M) and 2.5 volumes of ethanol. RNA was then precipitated by incubating the solution at −80°C for 1 h and centrifuging for 20 min at 16,100 × *g* and 4°C. The pellet was washed twice by adding 1 ml 75% ethanol and centrifuging for 10 min at 16,100 × *g* and 4°C. RNA was resuspended in RNase-free water, and the concentration was photometrically determined (59). Synthesis of cDNA was performed using SuperScript II Reverse Transcriptase (Invitrogen, Karlsruhe, Germany) with 5 μg of DNA-free total RNA, 250 ng random hexamer primers (Roche, Mannheim, Germany), and SUPERASE-In (Ambion Europe, Cambridgeshire, United Kingdom). The cDNA was used for PCRs, amplifying regions within the *algT-mucABD* gene cluster by using the following primer combinations: (1) algT_fwd, algT_revT7; (2) algT_fwd, mucA_revT7; (3) algT_fwd, mucB_revT7; (4) algT_fwd, mucB2_revT7; (5) algT_fwd, mucD_revT7_deg; (6) mucA_fwd, mucD_revT7_deg; (7) mucB_fwd, mucD_revT7_deg; (8) mucB2_fwd, mucD_revT7_deg; and (9) mucD_fwd, mucD_revT7_deg. Genomic DNA isolated from PG4180.muc served as a positive control. A reverse transcription (RT) reaction, where reverse transcriptase was omitted, served as negative control.

Determination of transcriptional start site. For primer extension analysis, ^{32}P-labeled primer mucD-Ps-3_pe (4 pmol) was annealed with 10 μg of total RNA, and reverse transcription was performed with M-MLV Reverse Transcriptase (Invitrogen). Nucleotide sequencing of 5 μg plasmid pBBR3-AXSalgTop with primer mucD-Ps-3_pe was done with the Sequenase version 2.0 DNA sequencing kit (USB) according to the manufacturer's recommendation. The extension product and sequencing reaction were resolved on a 6% polyacrylamide sequencing gel.

Determination of bacterial growth in planta. In planta growth of PG4180 and PG4180.muc was evaluated on soybeans (*Glycine max* cv. Choska). Soybean seedlings were maintained in a growth chamber at 24 to 25°C, 30 to 40% relative humidity (RH), with a 12-h photoperiod. Three- to 4-week-old plants were incubated at ≥92% RH for 48 h before inoculation. PG4180 and PG4180.muc were incubated for 48 h at 28°C on MG agar. Cells were suspended in distilled water, adjusted to an OD_{600} of 0.05 (approximately 5.0×10^7 CFU/ml), and applied to leaves with an airbrush (~8 lb/in^2) until the leaf surfaces were uniformly wet. Inoculated plants were grown in the greenhouse (20 to 25°C), and growth of bacterial strains was monitored by removing random leaf samples at 0 to 10 days postinoculation (three replicates per time point). Leaves were weighed separately and macerated in 5 ml sterile distilled water. Bacterial counts (CFU/gram fresh weight) were determined by plating dilutions of leaf homogenate onto MG agar and counting colonies after a 96-h incubation period.

Nucleotide sequence accession number. The nucleotide sequence of the *algT-mucABD* gene cluster of *P. syringae* pv. glycinea PG4180 was deposited in GenBank under accession no. DQ991248.

RESULTS

Alginate production of *P. syringae* pv. glycinea PG4180 and PG4180.muc. Strain *P. syringae* pv. glycinea PG4180 did not produce visible amounts of alginate when cultured on MG agar plates (Fig. 1A). In the process of screening for mucoid derivatives of PG4180, we identified PG4180.muc (Fig. 1A), which

FIG. 1. (A) Phenotype of *P. syringae* pv. glycinea strains PG4180 (1) and PG4180.muc (2) grown on MG agar plates at 28°C for 6 days. (B) Nucleotide sequence alignment and the corresponding amino acids encoded by the *algT* genes of PG4180 and PG4180.muc for the 5′ end of *algT*. The fourth codon (boldface letters) codes for glutamine (Gln) in PG4180.muc, whereas the respective codon in PG4180 leads to a nonsense (amber) mutation.

emerged spontaneously from a PG4180 culture. Quantification of alginate levels of both strains grown at 28°C for 96 h showed that PG4180.muc was able to produce larger amounts of alginate (106 μg alginate/mg protein) than nonmucoid PG4180 (2 μg alginate/mg protein, which was a negligible amount at the detection limit of the assay).

Nucleotide sequence analysis of the *algT-mucABD* gene cluster of PG4180 and PG4180.muc. To find out whether the phenotypic difference between PG4180 and PG4180.muc was due to changes in the *algT-mucABD* regulatory gene cluster, the nucleotide sequence of the insert of pBlueSK:AXSalgTop was determined (accession number DQ991248). The insert contained the coding regions of *algT*, *mucA*, *mucB*, *mucD*, and the upstream region of *algT*, which included the *nadB* gene. Sequence alignments with known *algT-muc* gene clusters showed the same general arrangement. In contrast to *P. aeruginosa* (7) and *A. vinelandii* (43), *mucC* was lacking in PG4180, PG4180.muc, and the closely related *P. syringae* strains FF5 (33) and DC3000 (8). Instead of *mucC*, PG4180 harbors an intergenic region of 283 bp between *mucB* and *mucD*, whereas in *P. aeruginosa* and *A. vinelandii* the intergenic region between *mucC* and *mucD* is just 40 bp and 11 bp, respectively. The PG4180 *algT* homologue is 582 bp (193 amino acids) and is closely related to *algT* from FF5, DC3000, and *P. aeruginosa* (99.5%, 99.0%, and 89.6% amino acid identity, respectively). Interestingly, the *algT* gene of PG4180 contained a single-nucleotide change at position 10, which resulted in a nonsense (amber) mutation in the fourth codon and thus the absence of a functional AlgT gene product (Fig. 1B). Sequencing of the *algT*, *mucA*, *mucB*, and *mucD* genes from PG4180.muc showed that the sequence was identical to that of PG4180, except that *algT* of PG4180.muc lacked the nonsense mutation. Therefore, this variant is likely to synthesize a functional AlgT gene product (Fig. 1B).

Complementation studies with *algT*. To determine if lack of alginate production in PG4180 is due to the nonsense mutation in *algT*, we cloned the intact *algT* gene, including its 988-bp upstream region from PG4180.muc, into vector pBBR1MCS-3, yielding pBBR3-AXSalgT. Plasmids pBBR1MCS-3 and pBBR3-AXSalgT were introduced into PG4180 and PG4180.muc. Transconjugants with plasmid pBBR3-AXSalgT clearly showed an alginate-overproducing phenotype when cultured on MG agar plates, whereas bacteria carrying vector pBBR1MCS-3 showed the same phenotype as their plasmid-free parental strains. Quantitative analysis of alginate levels confirmed that PG4180(pBBR3-AXSalgT) produced alginate (80.7 μg alginate/mg protein) in contrast to the control PG4180(pBBR1MCS-3) (3.7 μg alginate/mg protein). PG4180.muc(pBBR-AXSalgT) produced about 3.7-fold more alginate (353.6 μg alginate/mg protein) than PG4180.muc(pBBR1MCS-3) (94.4 μg alginate/mg protein). These results indicated that *algT* of PG4180.muc confers alginate synthesis.

Influence of functional *algT* on transcript levels of target genes. In *P. aeruginosa*, transcriptional activation of the biosynthetic *algD* operon and the *algT-mucABD* gene cluster depends on expression of AlgT (15, 21, 22, 27, 66). Whether AlgT of *P. syringae* pv. glycinea activates transcription of the *algT-mucABD* gene cluster and the *algD* operon was investigated by RNA spot blot analysis. Total RNA was isolated from PG4180, PG4180.muc, PG4180(pBBR3-AXSalgT), PG4180.muc(pBBR3-AXSalgT), and PG4180(pBBR1MCS-3) and analyzed with antisense RNA probes specific for *algT*, *mucA*, *mucB*, *mucD*, or *algD*, respectively (Fig. 2). Compared to its *algT*-deficient parent, the *algT*$^+$ strain PG4180.muc showed a transcriptional induction of 2.7-fold for *algT*, 2.6-fold for *mucA*, 1.4-fold for *mucB*, and 2.3-fold for *algD*. Interestingly, no induction for *mucD* was observed. Transconjugants PG4180(pBBR3-AXSalgT) and PG4180.muc(pBBR3-AXSalgT) showed a transcriptional induction of 37-fold for *algT*, 35-fold for *mucA*, 8-fold for *mucB*, and 4.4-fold for *algD*. As observed above, no significant induction for *mucD* was observed. These results suggested that the exceptionally high induction of *algT* and *mucA* in transconjugants carrying plasmid pBBR3-AXSalgT might be due to additional mRNA copies containing *algT*. Our results indicated that AlgT in *P. syringae* induces transcription of the *algT-mucAB* gene cluster and the *algD* operon, whereas transcription of the *mucD* gene does not depend on AlgT.

Transcriptional organization of the *algT-mucABD* gene cluster. Differences in the transcriptional levels of *algT*, *mucA*, and *mucB* as opposed to that of *mucD* in PG4180.muc indicated that the transcriptional organization might differ from the previously proposed operon structure (22). To investigate this, an RT-PCR-based approach was used to amplify different regions within the *algT-mucABD* gene cluster from PG4180.muc total RNA (Fig. 3B). DNA-free total RNA was transcribed into cDNA by use of reverse transcriptase. The cDNA was then used as template in PCR amplification reactions employing different combinations of primers (Fig. 3A). PCR products were obtained for those primer pairs which were localized either within the *algT-mucA-mucB* or the *mucD* gene regions. No products were amplified spanning the region between the *mucB* and *mucD* genes. These results suggested that *algT*, *mucA*, and *mucB* are located on a polycistronic mRNA, whereas *mucD* is transcribed into an independent mRNA.

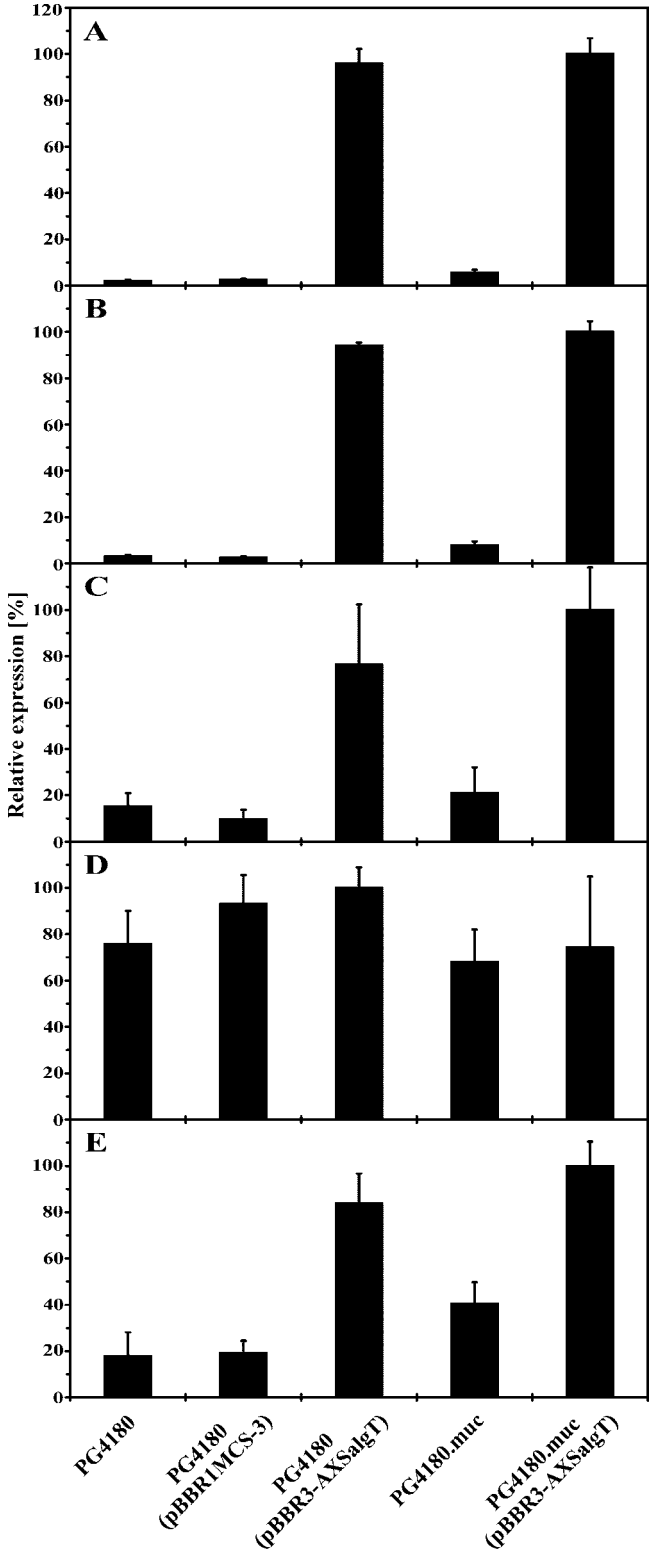

FIG. 2. Relative transcript abundance of the genes *algT* (A), *mucA* (B), *mucB* (C), *mucD* (D), and *algD* (E) in dependence of different *algT* genetic backgrounds. PG4180, PG4180(pBBR1MCS-3), PG4180.muc, PG4180(pBBR3-AXSalgT), and PG4180.muc (pBBR3-AXSalgT) were cultured in HSC medium at 28°C to an OD_{600} of 1.0. Total RNA was isolated and subjected to quantitative RNA spot blot analysis with *algT*-, *mucA*-, *mucB*-, *mucD*-, and *algD*-specific antisense RNA probes. The data represent the mean relative expression ± standard deviations (n = 4). Data were normalized to the highest expression value, which was set to 100%.

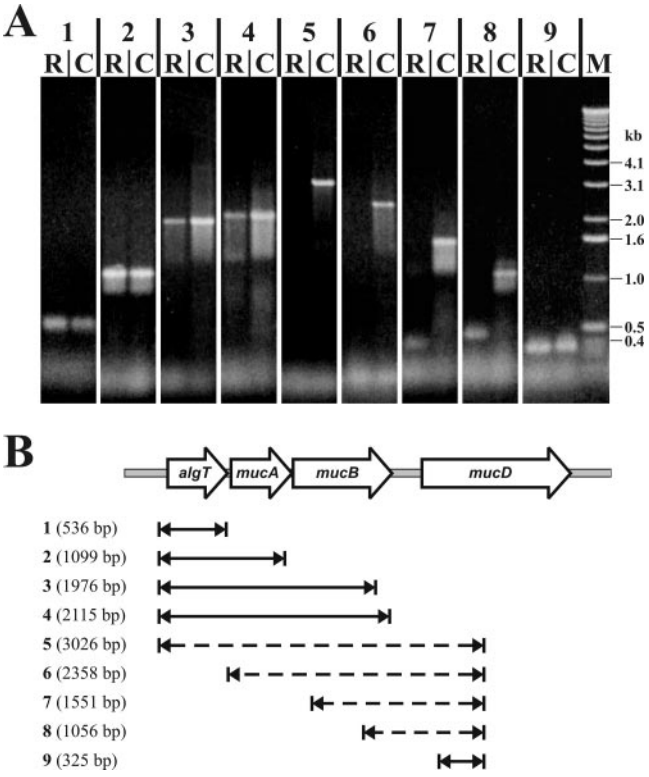

FIG. 3. RT-PCR analysis of the *algT-mucABD* gene cluster in *P. syringae* pv. glycinea. (A) Agarose gel with PCR products obtained from PG4180.muc cDNA (R) and PG4180.muc genomic DNA (C) as a positive control. For size estimation, a DNA size standard (M) was included. Numbers 1 to 9 represent the PCR products obtained by different primer combinations as described in panel B. (B) Schematic overview of length and location of the PCR products (1 to 9) within the *algT-mucABD* gene cluster. A solid arrow indicates that a PCR product was obtained from PG4180.muc cDNA, whereas a dashed arrow indicates that no PCR product could be obtained.

To gain further evidence for a separate *mucD* transcript, Northern blot analysis was carried out. In addition to the *P. syringae* pv. glycinea strains, we included one *Azotobacter vinelandii* and three *Pseudomonas aeruginosa* strains, which all possess an *algT-mucABCD* gene cluster. For increased and specific signals, equal mixtures of *mucD* antisense RNA probes, specific for *mucD* from *P. syringae*, *A. vinelandii*, and *P. aeruginosa*, were used for Northern blot hybridization. All strains showed a clear band of about 1.75 kb (Fig. 4). Comparison of the sizes of the predicted *mucD* open reading frames of *A. vinelandii* (1,422 bp), *P. aeruginosa* (1,422 bp), and *P. syringae* pv. glycinea (1,437 bp) with the observed *mucD* transcript sizes (~1,750 bp) indicated that *mucD* is likely to be transcribed as a monocistronic mRNA in all investigated strains. Interestingly, PG4180 showed a slightly higher *mucD* transcript level than PG4180.muc. Moreover, in both PG4180 and PG4180.muc, there was more *mucD* transcript observed

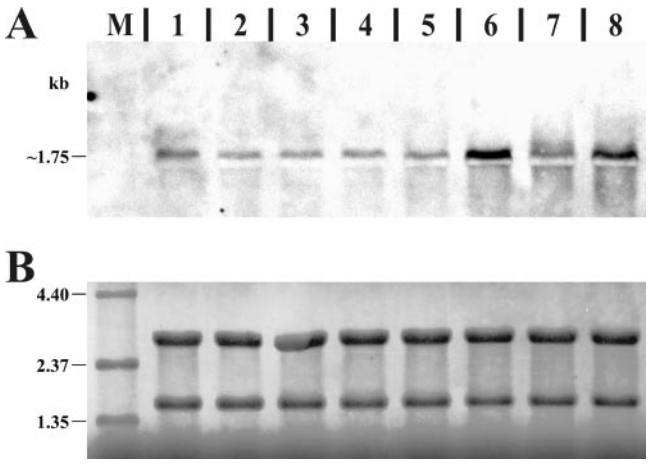

FIG. 4. (A) Northern blot membrane probed with a *mucD*-specific antisense RNA. The lanes contain 1.5 μg total RNA isolated from cultures grown to an OD_{600} of 1.0 from *A. vinelandii* wtC15 at 28°C (lane 1), *P. aeruginosa* Pa8821 at 37°C (lane 2), *P. aeruginosa* Pa8822 at 37°C (lane 3), *P. aeruginosa* Pa8830 at 37°C (lane 4), *P. syringae* PG4180 at 18°C (lane 5) or 28°C (lane 6), and *P. syringae* PG4180.muc at 18°C (lane 7) or 28°C (lane 8). The obtained signal, slightly above the 16S rRNA band, is marked with the estimated size. (B) Methylene blue-stained membrane prior to Northern blot hybridization for transcript size estimation, control of total RNA quantity, and successful Northern transfer. The same region of the membrane as that shown in panel A is shown. Distinct bands in lanes 1 to 8 represent those of the 23S (upper) and 16S rRNA (lower) or of the RNA size standard (3.0 μg) in lane M.

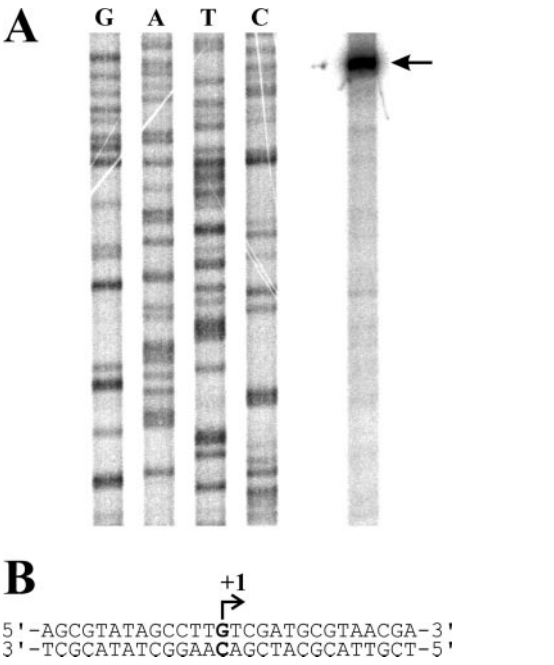

FIG. 5. Determination of the transcriptional start site of *mucD* in PG4180. (A) Separation of the results of nucleotide sequencing and primer extension reaction (black arrow) on a 6% polyacrylamide gel. (B) Nucleotide sequence surrounding the transcriptional start site (+1) of *mucD*.

when total RNA was obtained from cells grown at 28°C compared to cells grown at 18°C.

Transcriptional start site of *mucD* in *P. syringae*. Results of RT-PCR and Northern blot analyses prompted us to identify the transcriptional start site of *mucD* in PG4180. For this, primer extension experiments using total RNA from PG4180 and primer mucD-Ps-3_pe were carried out, resulting in a clear signal at nucleotide position −320 upstream of the translational start codon of *mucD* (Fig. 5). Interestingly, the potential transcriptional start site of *mucD* in PG4180 is located 37 nucleotides upstream of the *mucB* stop codon. It is further noteworthy that the 283-bp intergenic region between *mucB* and *mucD* is unique to various *P. syringae* strains but is not found in *P. aeruginosa* or *A. vinelandii*. Results were verified with two additional primers identifying the same nucleotide as the transcriptional start site of *mucD* in PG4180 (data not shown).

In vitro and in planta growth of PG4180 and PG4180.muc. Alginate synthesis in *P. syringae* is up-regulated by AlgT. Whether or not this influences in vitro or in planta growth was studied using strains PG4180 and PG4180.muc. For in vitro growth studies, bacteria were cultured in HSC medium at 18 and 28°C; 28°C represents the optimal growth temperature, while 18°C is a temperature where *P. syringae* pv. glycinea is most virulent. The OD_{600} was monitored continuously until cultures entered the late stationary phase (Fig. 6). PG4180.muc was impaired in its in vitro growth at 18 and 28°C compared to PG4180. This was most apparent in the extended doubling times (t_d) for PG4180.muc (t_d at 18°C, 8.9 h; t_d at 28°C, 5.4 h) compared to PG4180 (t_d at 18°C, 6.4 h; t_d at 28°C, 4.4 h).

In planta growth was evaluated by monitoring bacterial populations (Fig. 7) of PG4180 and PG4180.muc on soybean plants for 10 days. Within 10 days postinoculation, PG4180.muc induced clear symptoms in the form of water soaking followed by necrosis, which were significantly more pronounced than those induced by PG4180 (data not shown). Population dynamics

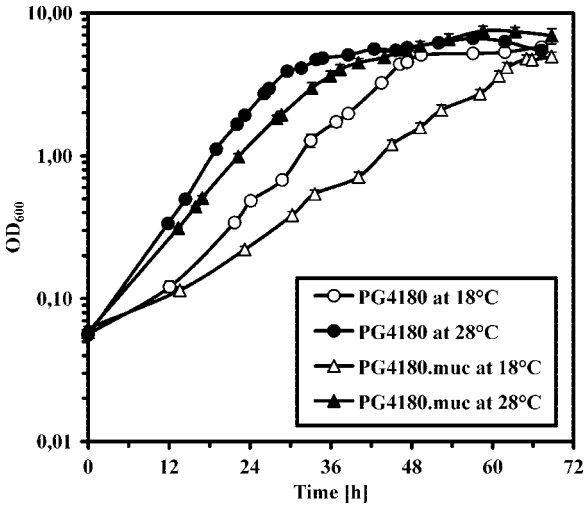

FIG. 6. In vitro growth of *P. syringae* pv. glycinea PG4180 and PG4180.muc in HSC medium at 18°C and 28°C as monitored by OD_{600}. Data represent the mean values of three independent cultures ± standard deviations.

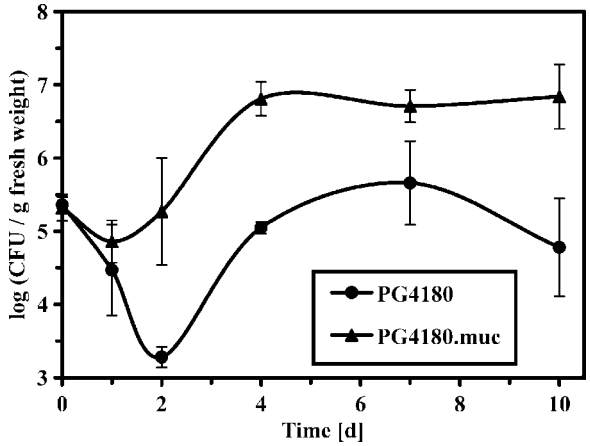

FIG. 7. In planta growth of *P. syringae* pv. glycinea PG4180 and PG4180.muc on soybean leaves. Bacterial strains (10^7 CFU/ml) were spray inoculated (~8 lb/in^2) onto soybean leaves until surfaces were uniformly wet. Data represent the mean values of three independent leaf samples ± standard deviations.

showed that both strains started with about the same number of CFU ($10^{5.4}$ CFU/g fresh weight) (Fig. 7). Afterwards, this number declined for PG4180 at day 2 by more than two orders of magnitude ($10^{3.3}$ CFU/g fresh weight). The difference in population size between PG4180 and PG4180.muc was most significant at day 2 postinoculation with almost two orders of magnitude and remained like this with little alteration until the end of the sampling period. The results suggested that PG4180.muc had a clear advantage in its ability to survive and maintain its population size on soybean leaves, in contrast to PG4180. The actual in planta multiplication rates during exponential growth (day 2 to 4) showed no significant difference. In summary, our results indicated that the presence of a functional *algT* gene is disadvantageous for the ability to grow in vitro but strongly promotes in planta survival of *P. syringae* pv. glycinea.

DISCUSSION

Most isolates of *P. syringae*, including *P. syringae* pv. glycinea PG4180, are nonmucoid (35). In *P. aeruginosa*, alginate genes are normally silent but can be activated by mutational changes in the *algT-mucABCD* gene cluster (43, 44). A respective model of a transmembrane apparatus consisting of the sigma factor, AlgT, its anti-sigma factor, MucA, and the anti-anti-sigma factor, MucB, had been proposed (44) and is widely accepted. In the present study, we analyzed how the non-alginate-producing strain PG4180 converted into its alginate-producing derivative, PG4180.muc. Sequence analysis of the *algT-mucABD* gene cluster of PG4180 showed the same gene organization as that of the closely related *P. syringae* pv. syringae strain, FF5 (33). Interestingly, *P. syringae* strains lack *mucC*, in contrast to *P. aeruginosa* and *A. vinelandii* (8, 33). In *P. aeruginosa*, *mucC* was required for survival in the presence of high salt and elevated temperatures, and in *A. vinelandii* it functions as a negative regulator for alginate biosynthesis (7, 48).

Absence of alginate production in PG4180 was due to a nonsense mutation in *algT*, which spontaneously reverted into an intact open reading frame resulting in a functional AlgT protein in the alginate-producing derivative, PG4180.muc. Complementation with *algT* cloned from PG4180.muc turned PG4180 into an alginate-producing strain, suggesting that alginate synthesis in PG4180.muc is solely due to a functional *algT* gene. The alternative sigma factor, AlgT, controls alginate biosynthesis in *P. aeruginosa*, *A. vinelandii*, and *P. syringae* pv. syringae (27, 34, 40, 43, 44, 66). While alginate production in PG4180 was turned off by a mutation in *algT*, in *P. aeruginosa* conversion to mucoid phenotype is often due to mutations in the anti-sigma factor *mucA* or *mucB* (44). As expected, additional plasmid-borne copies of *algT* converted PG4180.muc into an alginate overproducer, possibly due to an altered ratio of sigma factor versus anti-sigma factor. This result is in line with the broadly accepted model for induction and autoregulation of AlgT (57).

Based on different *algT* backgrounds, we studied transcription of selected genes known to depend on AlgT (16, 22). As expected, *P. syringae* transcription levels showed an autoregulation of *algT*, *mucA*, and *mucB* in bacteria producing AlgT, which furthermore resulted in activation of the alginate biosynthetic operon as measured by *algD* transcript levels. Our data are thus consistent with expression data obtained for *P. aeruginosa* and *A. vinelandii* (6, 51). Transcript levels for *mucD* were slightly higher in the *algT* mutant background, which contradicts the model according to which *mucD* transcription depends on AlgT and *mucD* resides on the same transcript as *algT* and *mucABC*.

The transcriptional organization of *mucD* within the *algT-muc* gene cluster was studied in more detail in *A. vinelandii*, *P. aeruginosa*, and *P. syringae*. Our primer extension experiment suggested that *mucD* is not part of the *algT-mucAB* operon in *P. syringae* but has its own transcriptional start site, which in fact is located 320 bp upstream of the *mucD* translational start site and within the 3′ end of the *mucB* coding sequence. The intergenic region between *mucB* and *mucD* is unique to *P. syringae*, suggesting that the situation might be different in *P. aeruginosa* and *A. vinelandii*. According to the *mucD* transcript sizes predicted in this study via Northern blot analyses and RT-PCR experiments, putative *mucD* promoters in *A. vinelandii* and *P. aeruginosa* might be located within the annotated *mucC* gene. For *A. vinelandii*, it had previously been proposed that *algT-mucABCD* is an operon, but no direct evidence was given (43). Recently, Firoved and Deretic (22) reported microarray expression data for AlgT-dependent genes in *P. aeruginosa*, where a significant gradient in expression levels for the *algT-mucABCD* gene cluster was observed. Highest expression levels for *algT* and lowest levels for *mucD* were interpreted as mRNA degradation starting from the 3′ end of the polycistronic transcript (22, 43). When those authors compared *mucD* transcription of the wild type and an *algT* mutant, *mucD* showed only a low 2.2-fold induction, while *algT* was induced 49.2-fold when AlgT was present. Our data furthermore confirmed results made recently by Wood and Ohman (65), who also reported an expression of *mucD* independent from that of *algT-mucABC* in *P. aeruginosa*. All these former results are therefore supportive to our findings, which allow us to speculate on the presence of two independent transcripts for *algT-mucAB* and *mucD* in *P. syringae*.

Elevated levels of *mucD* transcription in *P. syringae* at 28°C as opposed to 18°C indicated a potential role for MucD as a temperature-induced periplasmic protease (39). This is consistent with our preliminary observation that a *P. syringae* PG4180 *mucD* mutant is hindered in its in vitro growth at elevated temperatures (A. Schenk and M. Ullrich, unpublished data). Our findings support the hypothesis that *mucD* might act on AlgT or its regulators in an indirect way by removing periplasmic signals that activate the stress response system (6, 42, 67, 68). In consequence, the previously found impact of *mucD* mutations on the AlgT-dependent regulation of alginate synthesis (6, 43) might be rather indirect and might not be associated with the colocalization of *mucD* and *algT-muc* in the genome of alginate-producing bacteria. This speculation is supported by the fact that the *mucD* homolog *htrA* is located far distant from the *algT* homolog, *rpoE*, in the genome of *E. coli* (47).

Alginate production had previously been associated with several fitness traits in the plant-microbe interaction (17, 58, 69). Herein, we evaluated the impact of a functional *algT* gene on in vitro and in planta growth. The $AlgT^+$ strain, PG4180.muc, was impaired in growth in liquid medium, which was manifested by longer doubling times. In contrast, the *algT*-deficient strain, PG4180, showed better growth in vitro. Interestingly, results obtained in planta showed a clear advantage to survive and multiply for AlgT-producing bacteria. This is consistent with an earlier study where an alginate-deficient mutant of *P. syringae* pv. syringae was impaired in epiphytic fitness (69). Whether the advantage of PG4180.muc is only due to its ability to produce alginate or to other regulatory effects of AlgT needs to be addressed in more detail in future studies. AlgT promotes in planta survival of *P. syringae*, correlating with better bacterial growth, and therefore may be an indispensable regulator of natural fitness of *P. syringae*. According to long-lasting experience with PG4180, this strain was nonmucoid ever since it had been isolated from soybean plants in 1975 (R. E. Mitchell, unpublished data). We speculate that alginate production in *P. syringae* pv. glycinea might not be beneficial for all stages during the plant-microbe interaction. Synthesis of an exopolysaccharide is energy expensive and might hinder bacteria during particular periods, i.e., the onset of infection or rapid multiplication. During such periods, a single point mutation in *algT* might have rendered PG4180 ecologically fit and thus isolatable. It could be hypothesized that mixed populations of alginate-positive and alginate-negative cells might be of advantage for the complex infection process. Whether or not a typical genotype conversion takes place in *P. syringae* pv. glycinea and whether it is limited to mutations in *algT* remains to be elucidated and will be addressed in future studies.
