# The Chemical Content of Oklahoma Rainfall 

V. G. HELLER<br>Department of Agricultural Chemistry Research

## ACKNOWLEDGMENT

The investigation here reported was undertaken at the suggestion and with the assistance of C. P. Blackwell (deceased), Director of the Oklahoma Agricultural Experiment Station. The writer wishes to express appreciation of this cooperation and encouragement, also the assistance of those who faithfully collected and transported samples to this laboratory, as well as to C. E. Boatman, Ralph Cole, and George Dysinger, laboratory assistants, all of whom rendered valuable assistance in the analysis of samples.

## CHEMICAL CONTENT OF OKLAHOMA RAINFALL

V. G. HELLER

## INTRODUCTION

Considerable thought has been given to the problem of the depletion of Oklahoma farm lands during recent years. The chemical composition of the surface layers of tilled soils is constantly changing due to a number of factors. The harvesting of yearly crops of cereal or forage plants remove large quantities of both organic and inorganic constituents, and the annual loss due to washing and leaching by rainfall is suprisingly great. These losses are somewhat compensated by the addition of fertilizers from natural or artificial sources, by the growth of leguminous plants, and from another source usually overlooked, namely, rainfall. Many refer to rainfall as a pure source of water; this concept is erroneous, especially at certain seasons and locations. The question in regard to the importance of this contribution in our state has been raised, and as a result this department was requested to make an analysis of the rains from several typical sections of the state. The necessity of securing samples from a number of sources was emphasized due to the varied conditions in this state; the western section being a semi-arid area having no contaminating factory areas, but having frequent dust and electrical disturbances; the southeastern part of the state, on the contrary, receiving large rainfalls, having a more humid atmosphere, and being relatively free from contaminations of dust storms or factory wastes; the central and northeastern sections occupying an intermediate position as to depth of rainfall and dust, but undoubtedly receiving large quantities of smoke and fumes from oil fields, refineries, smelters and factories.

## Previous Studies of the Problem

Miller (1) in 1905, reviewed the early reports of many investigators and showed that in many cases considerable quantities of chemical compounds had been found present in most rain water. Nitrogen in the form of ammonia, nitrous, and nitrate, as well as other organic nitrogen forms were well known. Chlorides and sulfates have been generally reported, and in certain cases in considerable quantities; especially, is
this true in the vicinities of coal burning cities, and near large factories, refineries, and mills consuming large quantities of coal, gas or oil; in other instances, considerable quantities of inorganic metallic oxides have been found near smelters. After long periods of dry weather following excessive heat periods, and after dust and electrical storms, almost unbelievable quantities of impurities have been found in the first showers which washed the laden air. These are observations which have been repeatedly noted and recorded, both in this and in other countries for several years.

Miller, working at Rothamstead, England, found that in two years, 1888-89 to 1900-01, the average amount of ammonia plus the nitrate nitrogen per acre per annum was 3.84 pounds, 70 percent of which was in the form of ammonia. There was a variation of from 3.31 pounds to 4.43 pounds. The conclusion was that the variations probably depended in part on the distribution of the rainfall and had no definite relation to the quantity; however, the lowest was coincident with the least precipitation. It was further found that the amount of nitrogen depended on the temperature, since the magnitude of precipitation was greater in the summer months. It was also found that the quantity of nitric acid washed from the air in the two seasons remained constant, while the ammonia varied widely.

From 1890 to 1900, Harrison (2) analyzed the rain water collected at Georgetown, British Guiana. His analysis showed that 34.8 percent of the nitrogen was in the form of ammonia and 65.2 percent in the form of nitrates.

In Canada, Shutt (3) determined the quantity of nitrogen in rain and snow and found that the nitrogen increased with the use of bituminous coal. A total of 4.323 pounds of nitrogen per acre was precipitated, 74 percent of which was in the form of ammonia and the remainder as nitrates. The rain contained more nitrogen than snow.

In the rain waters collected at Lincoln, New Zealand, from July 1907, to June 1909, Gray (4) found an average of 1.548 pounds of nitrogen precipitated annually with 50.9 percent of the total for 1907-1908 as ammonia and only 44.6 percent as ammonia for 1908-1909.

In Russia, Vityn (5) estimated the amount of chlorine and sulfuric acid in water collected at eight different places from April 1909, to March 1910. The analysis was made on monthly samples. The average amount of chlorine was 11.355 pounds per acre, and that for $\mathrm{SO}_{3}$ was 29.49 pounds per acre.

Crowther and Rustan (6) concluded from their experiments at Leeds and Garforth that the ammonia content of rain water was largely determined by the locality and the amount of rain. Their analysis showed less ammonia in the summer than in the winter. Light rains were proportionately richer in ammonia than the more copious ones. There were 95.7 pounds of $\mathrm{SO}_{3}$ per acre added to the soil annually. One station at Leeds showed 336 pounds of $\mathrm{SO}_{3}$ per acre.

In 51 samples of rain and snow collected at Mt. Vernon, Iowa, in 1916, Artis (7) found that the ammoniacal nitrogen varied from 0.13 to 0.80 parts per million. Albuminoid nitrogen varied from 0.12 to 1.19 parts per million; the nitrate nitrogen from 0.005 to 0.80 parts per million. The chlorides ranged from 3.5 to 21.3 parts per million and sulfates ranged from 1.7 to 38 parts per million. The literature gave no data as to the quantity in pounds per acre and since there was no data relative to inches of rainfall it was impossible to calculate the annual precipitation of these substances.

Stewart (8) determined the sulfur in rain waters in Illinois. He found that 40 to 51 pounds per acre were washed down annually by the rain as shown by his analysis over a seven year period. The average was 45.1 pounds of sulfur per annum or 3.8 pounds monthly. The source of sulfur was from burning coal, sulfur dioxide and hydrogen sulfide that were liberated from industrial plants and growth of vegetation. He found that the amount of sulfur collected depended upon the quantity of rainfall. The amount added is sufficient to compensate for that lost through leaching and plant growth.

Wilson (9) found that, while the sulfur content was usually higher in industrial centers, sometimes the content was higher for agricultural districts.

Johnson (10) determined the quantity of sulfur in rain water in seven localities in Kentucky. The samples were collected at Lexington (U. S. Weather Bureau), the Van Meter farm near Lexington, Lincoln Institute, Paducah (Lone Oak), Mayfield, Russellville, and Greenville. The average rainfall was 44.77 inches, which furnished an average of 29.52 pounds of sulfur per acre per annum.

In New York, Wilson (11) analyzed samples from Ithaca, Brockport, and Alfred. An average of 7.13 pounds of ammonical nitrogen and .81 pounds of nitrate nitrogen from an average rainfall of 29.46 inches for an eleven year period was found at Ithaca. The amounts of ammonical nitrogen for

Brockport and Alfred over a three and a two year period respectively were: for an average rainfall of 31.7 inches and 32.4 inches, 2.6 pounds and 12.75 pounds. Over this same period the nitrate nitrogen for Brockport and Alfred were .23 pounds and .25 pounds respectively. The water at Ithaca furnished an average of 38.25 pounds of sulfur and those of Brockport and Alfred 77.53 pounds and 49.75 pounds respectively. The investigators verified the observation of others that the sulfur content was greater in the winter than in the summer. They observed that the amount of sulfur varies from station to station but remains constant at the same station.

Finnell and Houghton (12) furnished the only report of work done in Oklahoma. Their work was carried on at Goodwell, and the samples collected there were relatively free from industrial contamination. Their results show a greater quantity of ammonia when the rain is preceded by a dust storm.

Comparative results of these investigations will be found in Table 1.

TABLE 1.-Comparison of Chemical Content of Rainfall in Pounds per Acre as Previously Reported.

| Location | Period Collected | $\mathrm{NH}_{3}-\mathrm{N}$ | $\mathrm{NO}_{3}-\mathrm{N}$ | Total N | Sulfur | Chlorides |

Chemical Content of Oklahoma Rainfall

[^0]Fortunately, this Station has cooperating laboratories or field stations in several sections of the state. In each station were found men who were familiar with the methods and had equipment to collect and measure the rainfall. In a few cases farmers were instructed, and they faithfully cooperated during these studies. The location of these collecting stations and the persons cooperating are recorded in the following table.

| Location | Station | Collector |
| :--- | :--- | :--- |
| Woodward | Southern Great Plains Field Station E. F. Chilcott |  |
| Lawton | U. S. Dry Land Field Station | W. M. Osborn |
| Stillwater | Agricultural Experiment Station | Ralph Cole |
| Oklahoma City | Feed Control Laboratory | Charles Caskey, Jr. |
| Sand Springs | Chemist, Kerr's Glass Works | Raymond Gentry |
| Dewey | Chemist, Dewey High School | C. E. Boatman |
| Heavener | Experiment Station | Harry Cobb |
| Blackwell | Farmer | J. E. Moutrey |

The water samples were collected in porcelain or earthenware vessels which were placed on stiands away from trees or contaminating surfaces. The water was transferred to glass jugs and immediately expressed to this laboratory for analysis. A record of the amount of rainfall, the temperature, the direction of wind, and other interesting observations such as electrical disturbances and dust clouds were noted in each case.

The methods of analysis were, in most cases, those recommended in "Standard Methods for the Examination of Water and Sewage," American Public Health Association, New York, New York, Edition VI.

The compounds tested for and the methods used were:
Ammonia Nitrogen-by the distillation method; the only variation being the use of the ammonia color disc in the Hellige Acqua Tester.

Nitrite Nitrogen-by the sulfonilic acid a-naphthylamine acetate method, comparing the colors so produced to the nitrite nitrogen color disc.

Nitrate Nitrogen-by the phenol disulfonic acid method comparing to the Hellige nitrate nitrogen color disc.

Total Nitrogen-by the Kjeldahl (Gunning modified method) using the sample left from the ammonia determination. The total nitrogen being calculated from the ammonia and nitrate nitrogen and added to the Kjeldahl determination. In some cases the Kjeldahl was run direct upon a fresh sample by the use of the salycylic acid modification to include the nitrates.

Chloride-was determined directly by silver nitrate titration.

Sulfate-by the gravemetric barium sulfate method.
Each sample was analyzed separately and calculated. The sums of the separate determinations were added for the month's total. The latter was corrected for the month's total rainfall for this location as reported by the local weather station. This permitted the introduction of possible but unavoidable errors, due to the fact that the samples analyzed might not compare with the total rain that fell; the light first rainfall, invariably being more richly contaminated, and, also, due to the fact that the weather reporter was, in some cases, considerable distance from the collector.

The data for each station has been reported separately, and calculated in terms of pounds of material per acre, per month, and per rain. It should be stated that these figures were arrived at by the use of the following formula:

Content of rain analyzed expressed in pounds
per acre per inch $\times$ total rainfall per month $=$ pounds
per acre, per month.
This permits some error when the rain collected does not represent a true aliquot of the entire rainfall. This occurred when the inches gathered did not agree with inches reported by weather reporter.

## CONCLUSIONS

1. From the foregoing tables one must conclude that there are appreciable amounts of chemical compounds deposited by our annual rainfalls.
2. It will be observed that the ammonical nitrogen is greater during the spring months, after which it drops until early fall when it again rises.
3. That the greater percentage of chemical content is found in the limited rainfall after prolonged dry periods, after dust storms, and near industrial centers.
4. It was observed that the nitrate nitrogen increased after electrical disturbances, especially during the month of September.
5. The nitrite nitrogen is usually small and of slight importance.
6. The chloride content seems to be greater in the spring and fall, varying with the direction of the wind and the location.
7. The sulfates are surprisingly high and vary a great deal with the location and time of year. Samples collected at industrial centers are uniformly higher, suggesting contamination from fumes of burning oil, gas or coal.
