# Optimum Distribution Patterns For Feeder Cattle 

Max F. Bowser<br>John W. Goodwin

Cattle feeding in the United States has expanded rapidly during the past twenty years. The most rapid growth has been in areas outside the traditional North Central feeding states. Consequently, the market patterns for feeder cattle have changed substantially. As the number of different markets increases, feeder cattle producers must keep up with the changing conditions in order to optimize their marketing patterns. Only by keeping "on top" can they realize maximum profits.

Transportation costs from production areas to feeding areas are of major importance in the stocker-feeder business. Thus, any method which might help lower transportation costs would be especially important to the Western States where beef cattle are an important part of the agricultural economy.

In 1965 beef cattle and calves accounted for 22.7 percent of the agricultural cash income in the United States. Twenty-one states had cash income from beef cattle and calves greater than one-fifth of their agricultural receipts. Eleven states depended upon beef cattle and calves sales for more than one-third of their agricultural income. In Oklahoma beef cattle is the number one agricultural commodity. Only Texas had more beef cows in the two-year-old and over category in 1965 than did Oklahoma. With the exception of the Northeastern states, substantial numbers of feeder cattle are produced in all sections of the country, and cattle feeding is commonplace in thirty-two states. Many states have a surplus of feeder cattle while other states are deficit.

This study is oriented toward the importance of the relative advantages or disadvantages of different feeder cattle producing regions as they market cattle in the various demand regions, with given transportation rates. Truck costs were estimated for purposes of defining the minimum rates at which a trucker can haul feeder cattle.

## Feeder Cattle Distribution in 1965

The existing patterns of feeder cattle distribution in the United States in 1965 show the traditional patterns of movement and the recently observed changes. Traditionally, the Corn-Belt area of the North

Central Region of the United States has fed most of the cattle fattened for slaughter in the large terminal market areas of Sioux City, Chicago, Kansas City, etc.

Feeder cattle were shipped from the large grazing areas of Montana, the Dakotas, Wyoming, Kansas, Oklahoma, Texas and the Rocky Mountains states. With the advent of the local auction market and direct sales from ranch to feedlot, the numbers of cattle sold through the large terminal market have declined.

The Western States have increased their feeding capacities tremendously within the last decade. Thus, the large excess supply of feeder cattle once available has declined. The South and Southeastern regions of the United States now supply a large portion of feeder cattle into the Northern and Western feeding regions.

Another trend in cattle feeding is the emphasis on larger-sized feedlots. Sixteen states report the number of feedlots by size and number of cattle on hand January 1 each year. There were 56,191 cattle feeders in those sixteen states on January 1, 1965. Two and one-half percent of the feeders in the sixteen states had feedlots with a capacity of more than 1,000 head, but that two and one-half percent marketed sixty-five percent of the fed cattle in those states.

As the feeder cattle supply area expanded from the Great Plains and Rocky Mountain states to include the South and Southeastern states, the commercial feedlots, especially those in California, Arizona, Nebraska, and Colorado, began feeding many of the light weight mixed breeds or so-called "Okie" cattle from the South and Southeast. The pattern in 1965 showed higher quality calves from the Great Plains and Mountain states were still shipped to Midwestern feedlots. But the lower quality feeders from the South and Southeast move West and North to California, Arizona, Colorado, and Nebraska.

These feeding areas demand High Good to Choice finished beef, but results of experiments show that finished beef can be produced successfully from the so-called "lower grades" of feeder cattle. It seems entirely possible that more profits can be made from feeding "lower grade" feeder cattle into High Good or Low Choice grade slaughter cattle than from Choice grade feeder cattle because of existing price differentials.

## The Problem

During the 1960's the numbers of slaughter cattle marketed from feedlots increased tremendously throughout the United States. Not all
regions enjoyed the same rate of increase in fed-cattle production. The greatest relative increases have occurred in the Southern Plains and Western states. The North Central states, encompassing the traditional Corn-Belt production region, continue to produce a large share of the nation's fed beef, but their relative percentage of the total market has decreased within the past five years. The impact of this relative shift in production on feeder cattle distribution patterns may be of great interest to cattle men and cattle haulers alike as they strive to minimize transportation costs from production areas to feedlots.

Further, the development of the Interstate Highway System has made trucks the most frequently used mode of shipping cattle. Therefore, the problem is twofold. First, where should the producing areas ship their excess feeder cattle to minimize shipping costs and maximize profits? Second, what type transportation should be utilized?

## Objectives

The overall objective is concerned with defining the optimal shipping patterns and the changes that occur in those patterns as truck rates change. A secondary objective is to compare the optimal shipping patterns to the patterns of feeder cattle distribution as now established within the cattle feeding industry. Included in the total objective are several intermediate objectives:
(1) to define a regional demarcation of the United States for feeder cattle,
(2) to ascertain which feeding regions are deficit in feeder cattle production,
(3) to estimate the number of feeder cattle exported from or imported into each region,
(4) to show the differences between railroad rates and motor truck costs of transferring feeder cattle from production regions to alternative feeding regions,
(5) to find the volume and direction of trade between the surplus and deficit feeder cattle regions,
(6) to hypothesize what market patterns should become feasible as motor truck rates change, and,
(7) to project recent trends in the feeder cattle and cattle feeding industries to 1970 and predict the least-cost patterns of distribution under the conditions that might be expected to prevail in 1970.

## Method of Analysis

The linearly programmed transportation model was the main technique used to analyze the data collected. There are five basic assumptions associated with the transportation model.

1. The product or resources are homogeneous. This means that one unit of feeder cattle from one supply region will satisfy the demand in a deficit region just as well as will one unit of feeder cattle from an alternative source of supply. It is recognized that homogeneity of feeder cattle among all regions in the United States is the ideal rather than the actual situation of existing quality differences among regions. The cattle from the Southern and Southeastern states are reputed to have less feedlot potential than the range cattle from the Northern and Southern Plains' states. Since these suspected quality differences among regions cannot be accurately measured and quantified, the alternative assumption of homogeneity among regions was used. It is recognized that any real quality differences among regions might cause the true pattern of distribution to differ from the theoretical models.
2. The supplies of resources or products that are available at the various origins and the demand for the various destinations are known; total demand must equal total supply.
3. The cost (or profit) of (or from) converting resources to products or moving the commodity from origins to destinations is known and is independent of the number of units converted or moved.
4. There is an objective to be maximized or minimized. In this study the objective is to minimize transportation costs and to maximize profits for shipping feeder cattle to market.
5. Transportation from origins to alternative destinations can be carried on only at non-negative levels. This means that a region cannot ship more than it produces and that demand regions will not ship to other demand regions.

The above five assumptions can be also shown in equation form;

$$
\sum_{j=1}^{n} \sum_{i=1}^{m} x_{i j} C_{i j}=\operatorname{minimum}
$$

Subject to:

$$
\sum_{j=1}^{n} \quad x_{i j}=s_{i} ; i=1, \ldots, m
$$

$$
\begin{aligned}
& \sum_{i=1}^{m} \quad x_{i j}=d_{j} ; j=1, \ldots, n \\
& \sum_{i=1}^{m} s_{j}=\sum_{j=1}^{n} d_{j}
\end{aligned}
$$

and

$$
\mathrm{X}_{\mathrm{ij}} \geqslant 0 \text { for all } \mathrm{i}, \mathrm{j} .
$$

Where:
$\mathrm{X}_{\mathrm{ij}}$ represents the number of feeder cattle shipped from the $\mathrm{i}^{\text {th }}$ surplus region to the $j^{\text {th }}$ deficit region;
$s_{i}$ represents the number of feeder cattle available for export from the $\mathrm{i}^{\text {th }}$ surplus region;
$d_{j}$ is the number of feeder cattle demanded in the $j^{\text {th }}$ deficit region; and
$\mathrm{C}_{\mathrm{ij}}$ is the cost of shipping from the $\mathrm{i}^{\text {th }}$ surplus to the $\mathrm{j}^{\text {th }}$ deficit region.
In this study, the entire United States is considered for potential feeder cattle production and feeding. The potential numbers of feeder cattle which are expected to contribute the greatest share of the beef transportation problem will be emphasized. Therefore, the discussion in the following section eliminates most of the cattle which are not considered to contribute materially to the feeder cattle distribution problem.

## Demand and Supply Areas

## Demand Areas

The demand for feeder cattle for a given year is represented by the total number of fed cattle marketed the following year. That is, the demand for feeder cattle in 1964 can be closely estimated by the number of fed cattle marketed in 1965.

It is assumed that each region will supply its own demand before it ships cattle to other regions. If a region cannot satisfy its own demand, then it is referred to as a deficit supply area or a demand region. A region with a surplus of feeder cattle will ship to the deficit supply area (s) for which it has the greatest advantage or least disadvantage in shipping cost, relative to other surplus regions.

## Supply Areas

The supply is an estimated figure of the potential number of feeder cattle which each region, under current feeding practices and technology, would have available for meeting the feeder cattle requirements in the demand regions.

The potential supply of feeder cattle was computed in the follorwing manner. First, it was assumed that all "other" cows two years of age and over, as reported in the January 1 inventory report, supplied the calves for beef feeding. It was further assumed that all commercial calf slaughter was of dairy cow origin because many of the dairy states exhibit high calf slaughter numbers. A state-by-state estimate was made by multiplying the number of two-year-old-and-over other cows by the percent calving rate reported for all cows in each state in 1964. This produced a raw figure which had to be corrected to give a more realistic supply of feeder cattle in 1965. The death loss of calves as reported by the United States Department of Agriculture was deducted, an allowance for herd bull replacements, and then replacement heifers were considered at twenty percent of the reported numbers of "other" cows in the two-year-old-and-over category.

The second basic assumption of the general transportation model, which requires the total demand to equal the total supply, does not always exist for a given time period. An inequality of total demand and supply can easily be handled with a small modification to the transportation model. By using a dummy variable for either demand or supply, the equality condition is restored to the problem. The dummy variable is useful for handling imperfections in estimates or in available market data. If the total demand exceeds the total supply, a dummy supply variable will ship to any deficit region when all other supply is used up but there remains some unfulfilled demand. A high cost is associated with the use of the dummy supply so that the least profitable demand areas will be forced to use the higher cost supply.

In a similar manner, a dummy demand variable is used when the total supply exceeds the total demand. Unlike the dummy supply variable cost, the dummy demand has a zero cost associated with it. This simply means that once all real demand is satisfied, the excess supply is not shipped and thus adds no additional cost to the transportation solution. If the transportation problem is solved by linear programming techniques, the slack or disposal variable replaces the dummy demand variable, but the dummy supply variable must be inserted in the linear programming problem if all demand is to be satisfied.

For this study, the continental United States is divided into eighteen regions. Each region represents a geographical area somewhat homogeneous in its production and feeding capabilities and practices. Additional criteria considered for the regional demarcation included: (1) the natural barriers to transportation such as the Rocky Mountains, (2) the availability of data-in this case by whole states, and (3) the shipping distances. The smallest region by political breakdown is a single state, but most of the regions encompass two or more contiguous states. Figure 1 depicts the regional breakdown which was used for this study.

Where all of the above criteria could not be met for every region, a compromise was made among the dominant criteria affecting the particular region. It was also necessary to select a set of shipping points for each region. Ideally, the point should be near the center of the region's production or feeding area. It is assumed that the production units or feedlots are uniformly distributed about the representative point of each region. Table I gives the demarcation of states with the respective regional central shipping points.

## Transfer Cost Models

The total cost of transfer must be used in any analysis of transportation costs if realistic predictions of shipment patterns are to be made.

The price paid for feeder cattle at the point of origin is important because it represents the cost of an input for the demand region. If two

|  | Pennsylvania, Rhode Island, Vermont, |  |
|  | Delaware |  |

supply points are equidistant from a demand point, but the price of feeder cattle is higher at one supply point than the other, then the lower-priced supply point would have an advantage in shipping feeder cattle to the demand point in question.

The cash cost of production is a second transfer cost variable. Some regions have certain advantages for producing feeder cattle. Economies of size and small winter hay requirements, two factors which cause differences in cash cost of production, might be expected to cause one region to have an advantage over another region which is relatively the same distance from a specified demand point.

The third transfer cost variable, and probably the most important, is the enroute cost of shipping feeder cattle from the supply regions to demand regions. Where a supply region will ship its surplus feeder cattle depends to a large extent upon the distance to the demand region. Small differences in the price or cash cost of production cannot offset the shipping cost when differences in distances from supply to demand regions are several hundred miles. Not only is the hauling cost substantially different, but longer distances means additional shrinkage losses, and in many cases, longer return trips without a payload.

The three transportation cost variables can easily be incorporated into the transportation model. One can analyze the transportation cost
by using one, two or all three of the variables. To use the price and cash cost of production, simply choose one shipping center as a base and set it's price and/or cash costs equal to zero. Then compute the price and cash cost for every other region as the deviation from the price and cash cost in the base region.

The total transfer cost for each alternative shipping route for each supply region would be the summation of the variable costs considered in each region. Therefore, this study incorporates four transfer cost models to depict the impact of each cost variable separately and then together to predict the different patterns of distribution under the different transfer cost assumptions.

Model I. Model I simultaneously considered all three variables expected to affect the profitability of transferring feeder cattle from surplus to deficit regions. In this model, the analysis of optimum distribution patterns included the price, the cash cost of production, and the transportation charges for hauling the cattle between alternative supply and demand regions.

Model II. Model II considered only the price for feeder cattle plus the transportation charges between supply and demand regions.

Model III. Model III considered the cash cost of production for feeder cattle plus the transportation charges between supply and demand regions.

Model IV. Model IV analyzed the optimum pattern for distribution when just the transportation charges between surplus and deficit regions were considered.

Each of the four models has been used to analyze optimum patterns of shipment given the 1965 distributions of feeder cattle production and feeding. In addition, these models have been used to estimate optimal patterns for the expected 1970 distributions of feeder cattle production and feeding. The differences in these two sets of optima should give some indication of the areas which might be expected to have competitive strength or weakness for future marketing of feeder cattle.

## The Data

The reported number of cattle on feed marketed in 1965, which represented the demand for feeder cattle during 1964, was $17,593,000$ head. Fed cattle marketings during 1965 represented an increase of thirtysix percent over the number marketed in 1960 (see Table II). The estimated number of feeder cattle potentially available for feeding in 1965 was $17,978,543$ head - an increase of 24.9 percent over the numbers of feeder cattle potentially available in 1960 (see Table III).

| Total | 14275 | 15585 | 16158 | 17003 | 17950 | 17978 |

The relatively larger increase in the numbers of cattle demanded for feeding, compared with the percentage increase in the supply of feeders over the same period, is easily explained. Consumers have required progressively higher average grades of beef at the retail level. Fed beef tends to be much more uniform in quality than does non-fed
beef. Cattle feeding has also helped to stabilize the supply and the sources of beef for meat packers and chain food stores. More than half of all slaughtered beef in 1965 was fed beef. The remaining portion of slaughtered beef (or non-fed beef) was comprised of cull cows, cull bulls, and dairy cows. Grass-fat or range beef is a very small and declining portion of the beef industry.

## Demarcation of Regions

Each of the eighteen regions had regional supply and demand for feeder cattle (with the exception of Region 17 - the northeast - for which there was no available information concerning demand). The differences between the supply and demand were computed within each region. Seven of the regions had an insufficient local supply of feeder cattle for their feeding needs. The remaining eleven regions, while they did report feeding activity within their regions (except Region 17), produced a potential supply of feeder cattle in excess of what was being fed within their regions in 1965. Table IV gives the estimated potential regional supply and demand and the net differences within each region for feeder cattle in 1965. Figure 2 shows the geographical distribution of supply and demand regions in 1965 after aggregating the total supply and demand for feeder cattle within each region.

## Table IV-Estimated Regional Potential Supply and Demand for Feeder Cattle, 1965

Figure 2. Estimated Regional Net Inmovement and Net Outmovement of Feeder Cattle, 1965 ( 1000 Head).

## Truck Rates and Backhauls

The most common type of long haul rig used by cattle haulers in Oklahoma is the drop-center (or "possum-belly") semi-trailer with diesel tractor power. On short hauls, both the open-top semi-trailer and the "bob-tail" truck types are utilized.

Most of the cattle haulers interviewed in Oklahoma indicated that they were averaging in excess of 100,000 miles per truck annually. This large annual mileage greatly reduces the per mile costs for depreciation, federal use tax, licenses, insurance, administrative help, and capital investment.

The majority of long distance cattle haulers surveyed charged sixty cents per mile one-way for distances in excess of three hundred miles in length. Therefore, sixty cents per mile, one-way, has been used as the beginning point for this analysis.

A field survey was conducted to estimate the per mile cost of operating a possum belly-trailer combination headquartered in the Oklahoma area. The results of interviews with cattle haulers across Oklahoma, with two major manufacturers of tractors, and with three trailer manufacturers are shown in Table V. These cost estimates were for diesel trucks running an average of 100,000 miles per year. Information on operating

costs of smaller trucks and for trucks traveling less annual mileage may be found in the appropriate references in the bibliography. Since this study is concerned with interstate and interregional movements, the cost estimates for trucks operating under conditions similar to the data in Table $V$ are considered to be the most relevant.

A per-mile operating cost of $\$ .29$ for operating the truck and semitrailer leaves little room for profit at a $\$ .60$ per mile one-way rate if the trucker does not have backhauls.

Backhauls are desirable, but unfortunately are irregular, inconvenient, or seasonal in nature for many of the truckers. In addition, a small operator usually does not have the necessary contacts to insure regular backhauls.

Because backhauls definitely affect the competitive position of motor truck versus railroads, and because the carriers interviewed indicated that backhauls were available on about one-third of the cases, a back-
haul frequency of one-third was assumed. Without any backhauls the trucker would get $\$ .60$ for each mile, one-way. If he were able to get backhauls one-third of the time, he could charge a one-way rate of $\$ .46$ per mile, and still earn the same per mile income as with the $\$ .60$ rate without backhauls. Thus, the $\$ .46$ per mile rate was an alternative motor truck rate for which optimum solutions were computed. This reduction in rate recognizes that independent truckers will - when the possibility of backhauls exists - cut rates substantially in order to compete with other carriers for the available freight.

It also is appropriate to consider trucks to be fully loaded for long distance hauls. The forty-foot possum belly semi-trailer has the equivalent of a sixty-foot single deck trailer. An average weight of five hundred pounds per animal is assumed for all feeder cattle. Thus, sixty-five head will constitute a full load.

## Rail Rates

Although motor truck transportation accounts for most of the intrastate movement of cattle (Table VI), railroads still compete for the longer haul destinations. Actual point-to-point price rates were obtained for cattle shipments by rail. ${ }^{4}$ The standard for comparing railway charges with motor truck rates was a forty-foot by eight foot boxcar with a capacity for fifty head of five hundred-pound feeder cattle.

## Price of Feeder Cattle and Cash Cost of Production Variables

A second variable considered to affect the pattern of regional shipments was the price of the feeder animal. The prices for Good 500-800 pound feeder steers were determined from price data for markets in each region. The Good grade price was used because price data for

Choice grade feeder steers were not available for all regions. The price used for each region was a nine-year average for 1956-64. The price at Oklahoma City was defined as the base price. The prices for other regions were computed in terms of the differential from the price of feeder cattle in Oklahoma City (Table VII).

Theoretically, price differences between market points should approximate the transportation cost. This means that the further an area is from the terminal market, the lower the price must be in the shipping region to allow for the increased transportation cost. If this condition does not exist for two sales points, then either these sales points are in

${ }^{1}$ Estimated
separate market areas or there are other factors compensating for the transportation cost differential.

A third variable potentially affecting the competitive position of each region was the cash cost per hundred pounds of feeder animal produced. The cash cost is the most relevant comparative index of inter-
regional production efficiency and comparative advantage for feeder cattle production. To compute the cash cost of production, the following procedure was used. First, all annual inputs of expenditures were determined for a hundred-cow production unit. These annual inputs included: Native range, improved pasture, hay, feed supplement, minerals, veterinarian and medicine, bull depreciation, hauling and marketing cost, miscellaneous costs, interest, repairs and depreciation, taxes, and insurance.

Second, the value of the sale of cull cows was subtracted from the annual input expense. Third, the number of pounds of feeder cattle produced for sale was determined. Fourth, the annual input cost minus the value of cull cows was divided by the total pounds of feeder cattle to get the cash cost per pound of feeder animal. The cost of land was not considered because that cost often includes other factors such as mineral rights which have little to do with the agricultural productivity of that land. Oklahoma City was defined as the base point and the cash costs of production in other regions were computed as differentials from the cash cost in the region represented by Oklahoma City. Table VII gives the cash cost of production for each region. Figure 3 shows the specific areas for which the cash cost of production was computed. The cost of the specific areas within each region was used to represent the cash cost for the entire region.

Figure 3. Areas within Regions Used to Calculate Cash Cost of Production for Entire Region.

## Feeder Cattle Production

Feeder cattle are produced throughout the United States but production in the Northeastern and Lake States is small compared with that in other regions (Figure 4). The Southern Plains produce the largest share of feeder cattle, followed by the Central Plains and Western Corn Belt Regions. The South Central States and Northern Plains complete the five main areas of feeder cattle production.

The top ten potential feeder cattle producing states in 1965 were: Texas, Nebraska, Oklahoma, South Dakota, Kansas, Missouri, Montana, Iowa. California, and Colorado. However, the picture changes drastically when the individual state demands for feeder are considered. The heavyfeeding states such as California, Colorado, Iowa, and Nebraska actually are deficit supply regions since they feed more cattle than they produce. This problem is concerned only with surplus feeder cattle production which may potentially be shipped via interstate or interregional channels.

## Projection for 1970

A five-year projection of the trends in demand and supply represents a hypothesis of the relative shifts expected to occur in the regional production and utilization of feeder cattle. The projection of the numbers of cattle demanded for 1970 was derived by first considering the

Figure 4. Estimated Potential Supply and Demand for Feeder Cattle, 1965 ( 1000 Head).
numbers of feeder cattle demanded within the eighteen regions and for the United States for 1960 through 1965. A least squares regression function was fitted to these data. The trend was limited to $1960-65$ data since data for some regions were unavailable prior to 1960.

More data were available for analyzing the trend in production. Potential supply data were used for the years 1945 through 1964. Again a least squares regression function trend line was fitted to the data by regions and for the United States as a whole.

Production and utilization projections were computed for 1970 for each region and for the United States. Since the sum of the parts must equal the whole, the regional trend estimates were adjusted on a percentage basis such that the sum of the individual regional predictions would equal the expected total United States trend in both production and utilization (Table VIII and Figure 5).

## Results For 1965

## Model I

Model I analyzed the impact on the feeder cattle market pattern distribution from the eleven supply regions to the seven demand regions using simultaneous consideration of all three transport-comparative supply cost variables: mileage cost, local market price differential, and production cost differential.

Table VIII—Estimated Projected Regional Potential Supply and Demand for Feeder Cattle, 1970

| Region | Estimated <br> Potential <br> Supply | Estimated <br> Demand | Net <br> or |
| ---: | :---: | :---: | ---: |
| Supply |  |  |  |
| Demand $(+)$ |  |  |  |
| $(-)$ |  |  |  |

Figure 5. Estimated Regional Net Inmovement and Net Outmovement of Feeder Cattle, 1970 ( 1000 Head).

The rate for trucks was set at sixty cents per load mile, assuming no backhauls, and the problem of whether to ship by motor truck or by railroad and in what quantities was analyzed in each case. The results show that the railroads have a definite advantage in the cost of transportation in the absence of motor truck backhauls and should be utilized for all interstate movements except the relatively short ones. Figure 6 shows the geographic directions and the magnitudes of movements.

The Far West (Bakersfield) would be expected to receive about forty-five percent of its feeder cattle from the Billings and Ogden supply regions and the remaining fifty-five percent from the Oklahoma-Texas supply region. Phoenix would optimally receive all of its supply of feeders from the Oklahoma-Texas area. Oklahoma and Texas should also account for more than half of Denver's inshipments while Cheyenne should ship all of its available supply to Denver to fulfill Denver's demand.

In the Midwestern demand region of Omaha, the Oklahoma-Texas supply region would optimally account for eighty-four percent of the inshipments with the remainder coming from Pierre in the North and Jackson in the South. St. Paul would be supplied solely by the Pierre supply region. In the heart of the Corn-Belt states, Des Moines would draw heavily from the Southeastern quarter of the United States represented by the Louisville, Jackson and Thomasville supply regions. The

Figure 6. Interregional Flows of Feeder Cattle According to Model I with Truck Rate of \$. 60 Per Mile, 1965 ( 1000 Head).

Eastern Corn-Belt region of Indianapolis would be supplied by Louisville and Roanoke.

Because the total supply exceeded the total demand (that is, more cattle were produced than were fed), two supply regions would not have a feasible market for their small supplies under the postulated conditions. Spokane in the Northwest and Harrisburg in the Northeast would ship no feeder cattle at all in Model I.

## Model II

Model II analyzed the impact upon the optimum distribution pattern of feeder cattle when only the price differentials and transportation charges were used as determinants, assuming no motor truck backhauls and a truck rate of $\$ .60$ per load mile. The analysis of Model II indicated that without consideration for the cash cost of production, optimum shipping patterns are altered slightly. Railroads continued to have a substantial advantage in transportation cost over motor trucks except for the very short hauls. Figure 7 shows the geographic directions of the optimal distribution.

Bakersfield would be supplied by the Spokane, Ogden, Billings and Oklahoma-Texas regions with eighty-six percent of the inshipments coming from the Billings and Oklahoma-Texas regions. Again, the Okla-homa-Texas region should account for all needs in the Phoenix area.

Figure 7. Interregional Flows of Feeder Cattle According to Model II with Truck Rate of $\$ .60$ Per Mile, 1965 ( 1000 Head).

Denver would be supplied by the Oklahoma-Texas and Cheyenne supply regions as in Model I. In the Midwest, Omaha would continue to depend upon the Oklahoma-Texas supply region for most of its inshipments of feeder cattle, with Pierre supplying about fourteen percent of the feeder cattle for Omaha. Pierre was the only supply region expected to ship into the St. Paul demand area. In Model II, the Des Moines demand region again would receive most if its supply from the South and Southeastern regions of Louisville, Jackson, and Thomasville, but the Oklahoma-Texas region would also supply more than 100,000 head of feeder cattle to this region. The Eastern Corn-Belt region of Indianapolis again would optimally receive inshipments of feeder cattle only from the Louisville and Roanoke supply regions.

Without the cash cost of production differentials considered in the model, the transportation cost overshadows the relatively small price differentials among regions. Therefore, Spokane is close enough to Bakersfield to competitively supply Bakersfield. The Oklahoma-Texas region would ship fewer feeder cattle to Bakersfield under the conditions of Model II than those of Model I because of the entrance of the Spokane shipments to Bakersfield in Model II. Thus, the Oklahoma-Texas region has more feeder cattle available to ship to the Omaha and Des Moines regions in Model II.

Another difference in the results from Model II compared with Model I is that Louisville ships more feeder cattle to Indianapolis under
the conditions of Model II. Jackson ships its entire supply to the Des Moines region in Model II while discontinuing its shipments to Omaha. The Oklahoma-Texas region in Model II replaces the quantity supplied to Omaha by Jackson in Model I and in addition, Oklahoma-Texas exhausts its remaining supply by shipping to the Des Moines region. Because Oklahoma-Texas has taken part of the Des Moines market in Model II, a part which Louisville had in Model I, Louisville increases its shipments to Indianapolis, thereby decreasing the share of the Indianapolis market available for Roanoke.

The Northeastern supply region of Harrisburg still would not ship its small supply of feeder cattle under the conditions of Model II.

## Model III

Model III analyzes the impact of the differentials in cash costs of production and the transportation rate on the optimum pattern of distribution of feeder cattle marketings. Ignoring the possibility of truck backhauls, the results of the optimum problem solution for Model III show essentially the same distribution of feeder cattle as Model I except that Roanoke would ship to Des Moines as well as Indianapolis (Figure $8)$. The only other change is that Louisville would ship only to Des Moines in Model III rather than to both Des Moines and Indianapolis.

Figure 8. Interregional Flows of Feeder Cattle According to Model III with Truck Rate of $\$ .60$ Per Mile, 1965 ( 1000 Head).

As in Model I, neither Spokane in the Northwest nor Harrisburg in the Northeast would make any shipments under the conditions of Model III.

## Model IV

In Model IV the optimum feeder cattle market distribution was estimated using only the enroute costs of transportation. This model defines the least-cost array of shipments, with a truck rate of $\$ .60$ per load mile. The optimum solution for Model IV was identical with the distribution defined by Model II. This indicates either that the existing price differentials are in fact compatible with the optimum pattern that should theoretically prevail (i.e., that the price differentials do reflect transportation costs) according to the transportation cost, or that the influence of the transportation cost is such a dominant determinant of market patterns of feeder cattle shipments that the price differentials are inconsequential. Figure 9 shows the geographical directions of the distribution.

## Influence of Backhauls on the Optimum Solution

To this point, the optimum solution has been considered under the assumption that no backhauls were available to alter the revenue picture

Figure 9. Interregional Flows of Feeder Cattle According to Model IV with Truck Rate of $\$ .60$ Per Mile, 1965 ( 1000 Head).
for the motor truck carriers. Without backhauls, the trucker must charge enough when the truck is loaded to pay for the return trip.

The results of the $\$ .46$ per load mile charge for trucks, accounting for the presence of backhauls in about one-third of the cases while keeping the rail rate constant, suggest that current shipping practices of hauling most of the feeder cattle by truck are generally consistent with the expected economic optimum. Generally, the optimum shipping direction and patterns remain about the same as the $\$ .60$ per load mile charge for motor trucks, but with trucks replacing railroads in the majority of interregional shipments. Figures 10 through 13 give the results of the optimum model solutions with a truck rate of $\$ .46$ per load mile.

When the truck rate was decreased from $\$ .60$ to $\$ .46$ per load mile, some significant changes are worth noting in addition to the fact that most of the hauls shift to truck transportation at the $\$ .46$ per load mile rate. In the West, Bakersfield would be expected to receive only forty percent of Billings' supply of feeder cattle under the $\$ .46$ rate whereas it would receive all of Billings' supply at the $\$ .60$ truck rate. The Okla-homa-Texas region would substantially increase its supply shipments to Bakersfield to replace the reduced supply from Billings. Billings replaces the Oklahoma-Texas region as a source of supply for part of Denver's demand. The Bakersfield and Phoenix demand regions continue to be supplied entirely via railroad while the remainder of the United States is served by trucks except for a small shipment to Omaha from Jackson

Figure 10. Interregional Flows of Feeder Cattle According to Model I with Truck Rate of $\$ .46$ Per Mile, 1965 ( 1000 Head).
in Models I and III and a small shipment to Des Moines from OklahomaTexas in Models II and IV. Except for the specific cases just pointed out, the optimum solutions at the $\$ .46$ truck rate are identical with the quantities and patterns of shipments as the $\$ .60$ rate optimum solutions.

## Regional Patterns of Actual Feeder Cattle Distribution in 1965

California, (represented by Bakersfield in the analytical model) actually shipped very few nonfed or feeder cattle out of state in 1965. It had many more inshipments than outshipments and, therefore, was a deficit supply area. It received forty percent of its feeder cattle from Texas, sixteen percent from Arizona, ten percent from Oregon, eight percent from Nevada, four percent from New Mexico, three percent from Idaho, Oklahoma, and Utah, a few from Colorado and Kansas, and about ten percent from miscellaneous sources which were mainly the Southern states.

Arizona and New Mexico (Phoenix in the model) received the majority of their inshipments of feeder cattle from the Southern Plains and the Southeast. Arizona actually shipped over eighty percent of its 331,000 head of exported stocker-feeders into California and most of its inshipments moved into the two principal feeding areas around Phoenix and Yuma. New Mexico exported more feeder cattle than it

Figure 11. Interregional Flows of Feeder Cattle According to Model II with Truck Rate of \$.46 Per Mile, 1965 ( 1000 Head).
imported in 1965. Texas supplied fifty-five percent of Arizona's inshipments. The remainder of Arizona's inshipments came mostly from four other sources: about seven percent each from New Mexico and Oklahoma, fifteen percent from Old Mexico, and fourteen percent from the Gulf States. Texas supplied most of the inshipments to New Mexico while New Mexico exported the majority of its stocker-feeders into Colorado, Kansas, Oklahoma, and Texas feedlots.

Colorado (Region 7, represented by Denver in the analytical model), exported feeder cattle into every state bordering it but the main pattern of shipments moved east into Nebraska, Kansas and the Western CornBelt region. Colorado actually imports more stocker-feeder cattle than it exports which makes it a demand region as shown in the model. Colorado received thirty-nine percent of its inshipments from Texas, fourteen percent from Kansas, thirteen percent from New Mexico, nine percent from Nebraska, eight percent from Wyoming, seven percent from Oklahoma, small inshipments from Idaho and Montana, and seven percent from other sources in 1965.

The Nebraska-Kansas feeding region (Omaha) shipped very few feeder cattle to points outside its area but received large numbers of feeder cattle from Colorado, Texas-Oklahoma, Wyoming, and Montana in 1965.

Figure 12. Interregional Flows of Feeder Cattle According to Model III with Truck Rate of \$.46 Per Mile, 1965 ( 1000 Head).

Figure 13. Interregional Flows of Feeder Cattle According to Model IV with Truck Rate of $\$ .46$ Per Mile, 1965 ( 1000 Head).

The Corn-Belt states which comprise Region 12 (Des Moines) and Region 14 (Indianapolis) received inshipments of feeder cattle from Montana, Wyoming, the Dakotas, Colorado, Oklahoma, Texas, New Mexico, Alabama, Mississippi, and Tennessee in 1965. Table IX shows the trend of feeder cattle shipments into the North Central states by state or origin during recent years.

The results from the computer analysis of the transportation problem for 1965 - with but two exceptions - follow rather accurately the overall shift actually observed in the market pattern for shipping feeder cattle in the United States. The analytical model indicates that Montana should be expected to ship much of its supply into California. The data on livestock movements show that Montana in fact ships most of its cattle into the Midwest or North Central states and very small amounts into California.

The model also shows that Wyoming (Region 6) should ship mostly into Colorado but the movement data indicate that Wyoming has its largest market in Nebraska and the Western Corn-Belt region. These differences between the actual shipping patterns and the theoretical model are most likely explained as a weakness of the assumption concerning homogeneity of feeder cattle among regions. As was indicated previously, the homogeneity assumption represents an ideal situation rather than one which actually exists.

The feeder cattle from the Northern Plains region tend to be the high quality, "reputation" type of animals which have traditionally been placed on feed in the Corn-Belt. The tendency of Corn-Belt feeders to demand the higher quality animals is partially illustrated by the fact that Corn-Belt terminal markets have normally exhibited the highest average prices of any region in the United States (see Figure 14). California's average price for the higher grades of feeder cattle is lower than the average price for those grades in the Corn-Belt region; therefore, Montana tends to ship her high quality cattle to the higher priced area. For the same reason, Wyoming ships into the Corn-Belt region rather than into Colorado. California and Colorado both have adequate sources of feeder cattle inshipments at lower prices than Montana and Wyoming.

Thus, the Southern Plains are in a very favorable position to supply California and Colorado. The analytical model considers only the net movement of feeder cattle between regions, and, therefore, the solution will only show the particular region either as a deficit or surplus region.

Figure 14. Average Prices for Good 500-800 Pound Feeder Cattle From 1956-64 for Various Markets in the United States. Source: U. S. Department of Agriculture, AMS, Livestock Division Market News Service.

This assumes that local demand will be supplied by local supply, if it exists, before requiring inshipments. There is no accurate means for analytically estimating the extent to which different regions exchange supplies. Obviously, those cattle produced near state lines can be marketed in either of the two states concerned with about equal facility.

## Cost Analysis of Models for 1965

The preceding discussion outlined the general optimum shipment patterns for the different models in terms of quantities shipped and the geographical distribution. Each of the optimum solutions also specified the transfer cost per hundredweight and the cost ranges over which the optimum solution remains unchanged.

A detailed explanation of two model solutions will illustrate the usefulness of the cost ranging information contained in the linear programming solution. The illustration will begin with a truck rate of $\$ .60$ per mile for 1965 quantities and then compare the changes which occur as the truck rate decreases to $\$ .46$ per mile for 1965 quantities.

The first model solution considered is Model IV with a truck rate of $\$ .60$ per mile. Starting from the left side of Table $X$ the first three columns of Origin, Destination, and Quantity Shipped are self-explana-

Table X—Cost Analysis of Model IV Optimum Solution with Truck Rate of \$.60 Per Mile, 1965

[^2]tory. The column headed "Transfer Cost/Cwt." gives the present transfer cost for shipping one hundred pounds of feeder cattle from the corresponding origin to the designated demand point. The next four columns come under the general heading "Cost Range over which Optimum Solution Remains Unchanged." In other words, the last four columns give the interval within which the transfer cost may vary without generating a change in the optimum solution.

Should the cost of transfer be outside he specified interval, the sixth and eighth columns define the first change that would be made in reaching a new optimum. If, for example, the cost of shipping from Oklahoma City to Bakersfield should decrease by $\$ .15$ (i.e., if the cost should fall from $\$ 1.55$ to $\$ 1.44$ ) per hundredweight, Billings will begin shipping to Denver by rail.

At the other end of the interval, if the rate from Oklahoma City to Bakersfield should increase to $\$ 1.78$ per hundredweight (an increase of $\$ 0.19$ ) , Jackson will begin to ship to Bakersfield by rail, thus partially replacing Oklahoma City in the Bakersfield market. When an incoming vector gires the name of the shipping point followed by the word "UNUSE," this indicates that that particular shipping point is forced out of competition and has no feasible market to which to ship its feeder cattle. Any shipment route which has an "INFINITE" lower limit will continue to ship to the same point as in the current optimum solution regardless of any decrease in the shipping cost.

Two generalizations may be drawn concerning the cost range from the liest Coast to the Eastern Corn-Belt. For all model solutions, the cost ranges over which the optimum solution remained unchanged were very wide on the West and East coasts but very narrow (i.e., sensitive to change) through the mid-section of the country. If the rates were to increase or decrease by $\$ .05$ per hundredweight or less for five different shipments into the Great Plains or the Corn-Belt, the optimum solution would change. The second generalization is that the optimum solution is more sensitive to change from rate increases than rate decreases.

The optimum solution for Model IV with a truck rate of $\$ .46$ per mile for 1965 quantities gives the same general geographic distribution of shipping as with the $\$ .60$ per mile rate for trucks (Table XI). The primary difference with the lower truck rate is that most of the shipping is done by trucks whereas the $\$ .60$ truck rate caused most shipments to be sent by railroad. Another difference (other than a reduction in the "transfer cost per cwt." column) is that as the truck rate is decreased, the interval for cost changes is likewise reduced.

*Railroad shipments.

The second model considered in detail is Model III. The overall geographic distribution for Model III as shown in Table XII is much the same as Model IV. However, the cost figures per hundredweight transferred include an additional cost variable - cash cost of produc. tion. In general, the costs for Model III are greater than Model IV because of the inclusion of this variable. However, the same pattern as for Model IV was exhibited by Model III. There were wide transfer cost ranges along within which the solution was stable. But very small changes in transfer costs in the nation's midsection would generate a new solution. Model III also exhibits a greater sensitivity to truck rate increases than to rate decreases.

Much the same conclusions can be drawn from the Model III solution as the truck rate is decreased to $\$ .46$ per mile as for the Model IV solution at the $\$ .46$ per mile truck rate. The Model III solution cost analysis for 1965 with a truck rate of $\$ .46$ per mile is given in Table XIII.

The transition from the linear programming results of the optimum shipment pattern to the transportation problem type of tableau can be made easily. Table XIV illustrates the otpimum shipments of Model IV, with the $\$ .46$ truck rate, for 1965 quantities in the general transportation type tableau. To determine the supply of each origin, merely sum across the columns for a particular row. The total supply from each origin is given in the right-hand column of the table. The demand for each destination is found by summing down the rows for a particular column. The total demand of the deficit feeder cattle regions is given in the bottom row of the table. If the bottom row and the right-hand column are each summed, the totals should be identical. Therefore, the condition exists that total demand equals total supply.

The shadow prices which are associated with the optimum solutions are useful for defining which supply regions are very near to entering the least cost solutions. In other words, if a region is hard pressed to purchase feeder cattle from normal sources, the shadow price will suggest the next best alternative source of supply. The cost analyses indicated the cost ranges over which the activities in the optimum solution could vary, but do not indicate how competitive alternative shipping routes are with respect to the ones appearing in the optimum solution. This information may be obtained from the shadow prices included in Appendix C.

## Analysis Of Results For 1970

Because the rate of increase in the demand for feeder cattle has been greater than the rate at which supply has increased, demand as projected for 1970 exceeds the projected supply for that year. Demand and supply could be forced into equality either by adjusting demand downward or by adjusting supply upward. The reasoning underlying such an assumption would be that no more cattle could be fed than were supplied. However, equating demand and supply by this means to a degree perdetermines the results and does not adequately show which regions have the greatest competitive strength for purchasing or supplying feeder cattle.

An alternative manner of handling the problem of demand exceeding supply and the one selected for use in this study is to assume that each region will continue its present trend in demand until 1970, with no adjustment forcing total demand to equal total supply. This assumption allows the most profitable demand or feeding areas to use all available supplies of feeder cattle first. A dummy supply activity is placed in the model in order to equate total demand with total supply. Since the model requires that all demand must be satisfied, the dummy supply is needed to satisfy the demand in the less competitive regions. A high cost is associated with the use of the dummy supply in order to show that the region which uses it must endure abnormal costs to maintain
their projected feeding rate. The high-cost demand areas will be forced either to scale down their feeding activity or increase local production in order to meet their needs.

## The Model Solutions

Models I, II, III, and IV all gave identical geographical optimum patterns of distribution of feeder cattle without regard to truck rates. The shift from predominantly rail to truck transportation again occurred when the truck rate decreased from $\$ .60$ to $\$ .46$ per load mile. This indicates a stable pattern of distribution over a substantial range in the rates for truck transportation (see Figures 15 and 16).

The results of the optimum solution for the 1970 projection and the geographical directional distribution are shown in Figure 15. The Bakersfield (California) and Phoenix (Arizona and New Mexico) regions are likely to be the least profitable regions to which to ship cattle by 1970. In fact, three-quarters of the shipments to Bakersfield come from the high-cost dummy variable. Phoenix receives forty percent of its supply from the dummy activity. Oklahoma-Texas no longer finds it profitable to ship feeder cattle to California under the conditions of this model. However, California, Arizona and New Mexico are still likely to have access to a limited supply of feeder cattle not considered in the model - those from Mexico.

Figure 15. Interregional Flows of Feeder Cattle According to Models I, II, III, and IV with Truck Rate of $\$ .60$ Per Mile, 1970 (1000 Head).

The Northwest and Ogden would be expected to ship all available surplus supplies into California. Billings would ship to California only after Colorado requirements had been satisfied. Oklahoma City would supply Phoenix with limited quantities of feeder cattle, but only after exhausting its market opportunities in the Omaha region. Denver would receive all of its supply from Wyoming and Montana. The OklahomaTexas area would supply about three-fourths of Omaha's demand for more than two million feeder cattle, with the remainder coming from Pierre and Jackson. St. Paul still receives the majority of its supply from Pierre but Harrisburg ships all of its available supply to St. Paul. The Corn-Belt regions of Des Moines and Indianapolis receive their entire supply of inshipments of feeder cattle from the southeastern areas - designated in the model as Jackson, Louisville, Thomasville, and Roanoke.

The potential total supply of feeder cattle for 1970 is expected to increase about fifteen percent over that of 1965. However, the total demand for feeders is expected to increase by about twenty-eight percent over the same five-year period. Not all regions are expected to show demand and supply shifts parallel with the total shifts. Some regions will continue to increase but decrease in relative standings with the other regions. Other regions will actually decrease in their demand or supply potential. The expected relative shifts in regional supply and demand are shown in Table XV.

Figure 16. Interregional Flows of Feeder Cattle According to Models I, II, III, and IV with Truck Cost of \$.46 Per Mile, 1970 ( 1000 Head).

## Cost Analysis of Models for 1970

When the Model III and Model IV optimum solutions for the projected 1970 quantities are examined in a manner similar to that discussed for 1965, the cost ranges suggest that when demand exceeds supply, the optimum solution is stable within somewhat smaller intervals than when supply exceeds demand. The 1970 Models III and IV optimum solution analyses are shown in Tables XVI, XVII, XVIII, and SIX.

Table XX illustrates the optimum shipments of Model III and IV for 1970 quantities in the general transportation type tableau which was previously explained for the 1965 results.

## Summary

This study was made to analyze the U.S. feeder cattle industry and to estimate the present and future optimum patterns of feeder cattle distribution. The United States was segmented into eighteen regions for which the potential supply (production) and demand (feeding) quantities of feeder cattle were computed. Each of the eighteen regions was designated either as a "supply" region (with local production of feeder cattle exceeding local feedlot needs) or as a "demand" region (with the volume of feeder cattle used in feedlots exceeding local feeder

cattle production). When the supplies and demands for feeder cattle within each of the eighteen regions were aggregated, there were eleven surplus and seven deficit feeder cattle regions.

The analysis was conducted using both truck and rail transportation. The primary motor truck used for this study was the diesel tractor with a forty foot possum-belly semi-trailer. Cattle haulers were interriewed to determine the prevailing motor truck rates for hauling feeder cattle. Rail rates were obtained from the regional offices of the A T \& S F Railway in Wichita, Kansas.

Simultaneous transportation solutions for truck and rail transport were obtained for the distributions of feeder cattle production and cattle feeding as observed in 1965. Although a specific study on backhauls was not made, their importance is considered to be a prominent factor in present competitive conditions in the transportation of feeder cattle. Backhauls were available to the surveyed truckers about one-third of the time and were reflected by an appropriate adjustment in the hauling rate.

Four theoretical models were used to analyze optimum distribution patterns. The optimum distributions of Models I, II, III, and IV depicted patterns that were very similar for both the truck rate of $\$ .60$ and $\$ .46$ per mile. Since the quantity transported and the transportation charges were included in all four models, and since the optimum patterns were essentially the same for all models, the overwhelming factors for
determining optimum patterns of feeder cattle distribution are the weight of the shipment and the distance between the supply region and alternative demand areas.

In general, variables such as production costs and price differentials did not alter the pattern. For 1965, the optimum patterns for feeder cattle shipments is generally as follows: The Pacific Northwest, Utah, and Nevada should ship all of their export supply of feeder cattle into California feedlots. If feeder cattle were in fact homogeneous among regions, the Montana area should also ship its feeder cattle by rail into California and by truck into Colorado, but because of quality differences, this area has in fact shipped most of its cattle into the Nebraska and Iowa areas.

The Southern Plains region, the largest supplier of feeder cattle, would be expected to ship about half of its feed cattle exports into California, ten percent into the Arizona-New Mexico region, thirty-six percent into the Kansas-Nebraska area, and about four percent into the Western Corn-Belt region.

Other studies have shown that more than half of the Southern Plains' outshipments of feeder cattle actually moved into California, Arizona, and Colorado during 1965. More than thirty percent of Texas’ outshipments were shipped into California, but the remaining portion of the Southern Plains' outshipments moved North and Northeast into Kansas, Nebraska, Iowa, and Illinois.

The Model solutions and the actual data both show that the Dakotas ship feeder cattle into Minnesota, Nebraska and the Western Corn-Belt regions. Optimally, Colorado should be supplied by Montana and W yoming. It appears however, that Colorado receives about sixty percent of its inshipments from Texas, New Mexico, and Oklahoma. For the most part, the South Central and Southeastern regions should ship feeder cattle into the Western Corn-Belt feedlots while the MidAtlantic and Appalachian regions should ship into the Eastern CornBelt feedlots. Under the conditions in which supply of feeder cattle exceeded demand for them, the small supplies of feeder cattle in the Northeastern states did not have a feasible market.

The main difference in the 1970 optimum pattern of distribution from the 1965 optimum pattern is that shipments from the OklahomaTexas area into California would be expected to virtually cease. However, estimated shipments from the Oklahoma-Texas region into the Kansas-Nebraska area would nearly double. Arizona and California may experience disadvantages in obtaining feeder cattle by 1970. The im-
portance of the feeder cattle supply from the South Central and Southeastern states will become increasingly important to the Corn-Belt regions by 1970. With the abundant supply of local feeder cattle, large efficient feedlot operations, adequate feed grain supplies, and excellent nearby markets for both excess feeder cattle and fed beef, the TexasOklahoma region occupies a very prominent position in the beef sector of our economy in the 1965 and 1970 optimum solutions.

The growth of the cattle feeding industry in the Southwestern states during the last five years tends to coincide with the results of this study. According to studies made by Goodwin and Uvacek, Oklahoma and Texas have increased their cattle feeding capabilities tremendously from 1960 to 1965, and are expected to continue to increase even more rapidly in the near future. The large supplies of good feeder cattle, which were once available from the Texas-Oklahoma region for shipment into the Corn-Belt and California regions, will be greatly reduced as local feeding increases within the Texas-Oklahoma region. The Southern Plains are in an excellent location to utilize the large supplies of local feed grains necessary for feeding locally produced cattle.

## APPENDIX C

The following code information will interpret the numerical and alphabetical regional designations of Appendix G tables on the shadow prices for the optimum model solutions for this study. Any three-digit number beginning with a "three" will indicate a rail supply shipment. A three-digit number beginning with a "two" will indicate a truck supply shipment. All three-digit numbers beginning with a "one" will indicate a demand region. An asterisk to the left of a shipment will indicate that activity is in the optimum solution. The plus signs preceeding the shipment designations indicate the slack activity for each of the supply regions. A slack which has an asterisk preceeding it shows that all of that region's supply was shipped.

2.36929000

This states that an additional truck shipment from Spokane to Bakersfield would add $\$ 2.36929$, per hundredweight of feeder cattle shipped, to the optimum least cost solution.
