## ACKNOWLEDGEMENTS

The writer wishes to express his appreciation to the staff of the Agronomy Department of Oklahoma State University for their helpful advise and constructive criticism. Special acknowledgement is expressed to Dr. J. Q. Lynd for his inspiration, encouragement and helpful criticisms in connection with this research study and in preparation of this thesis. The writer also wishes to thank Dr. Wayne W. Huffine, Dr. Lester W. Reed and Dr. Billy B. Tucker for suggestions and criticisms; Mrs. Cheryle J. Moxley and Mrs. Marilyn A. Jackson for typing the manuscript; and to my wife, Velta Jo, for her assistance in preparation of the thesis and for proofreading the final copy. Special gratitude is given the Agronomy Department for the Research Assistantship granted the writer.

## I INTRODUCTION

Alfalfa is among the most important perennial forage crops produced in Oklahoma. Continued successful production of this legume is dependent on sound management and soil fertility practices adapted to each of the several soil and climatic areas within the state.

A soil fertility research study with alfalfa was initiated by the Oklahoma Agriculture Experiment Station in 1955. Results from these experiments have contributed information necessary for improved management and maintenance of alfalfa on important alfalfa producing soils in central and eastern Oklahoma.

The objective of these field and greenhouse studies was to determine the response of alfalfa to various soil fertility treatments. Treatments used in the field experiment at the Thomas farm included three rates of phosphorus, two rates of potassium and two rates of boron. Those treatments used at the Paradise farm included five rates of phosphorus, two rates of potassium and two rates of boron.

The greenhouse experiment was concerned with calcium and magnesium ratios applied with and without phosphorus and potassium fertilizers.

## II REVIEW OF LITERATURE

Establishment and maintenance of alfalfa under Oklahoma soil and climatic conditions are dependent on successful management and soil fertility practices. Yields, hay quality and stand maintenance are greatly dependent in most areas on favorable soil conditions. Alfalfa has a high requirement for available plant nutrients from the soil (11)<sup>1</sup>.

Lucas and Scarseth (18), with data from various plant sources converted the percentage of K, Ca and Mg to a chemical equivalent basis. A reciprocal relationship was found to prevail between the K, Ca and Mg in the plants. This relationship helps to account for the need of potassium in sorghum.

Schmehl et al. (34) studied the influence of soil acidity on the absorption of calcium by alfalfa, with radio-calcium. They reported the rate of absorption of calcium by alfalfa was markedly reduced in the presence of aluminum ions. It was reduced to a lesser degree in the presence of manganese and hydrogen ions of a nutrient solution. They suggested the low calcium content usually observed in plants grown in an acid soil may be due to the antagonistic effect of aluminum manganese and hydrogen ions on the absorption of calcium ions, rather than a low supply of calcium in the soil.

---

<sup>1</sup> Figures in parenthesis refer to Literature Cited.

Winter survival of alfalfa is closely related to soil fertility. Wang (41) found that in most cases, the additions of lime or lime and other fertilizers, increased the water retention of alfalfa by increasing the water soluble protein content of the plants. This capacity for retention of water appears to be directly related to the ability of alfalfa to withstand winter killing.

Overliming of alfalfa is usually accompanied by reduced yields. According to Turk and Lynd (39), overliming not only reduces yields but it also reduces the percentage of potassium, manganese and phosphorus in the plants and increases the calcium content. In an investigation with legumes, Lynd and Turk (19) were able to prevent overliming injury by the application of manganese sulfate. They found a marked decrease in exchangeable manganese in the soil with increasing rates of lime. The quantity of exchangeable potassium and absorbed phosphorus was not appreciably affected.

Liming of alfalfa to optimum pH levels is closely related to yield. Moser (24) showed the calcium supplied at low pH values was a more important growth factor than the pH value. His results indicated that calcium supplied in increasing increments gradually increased in the plant, reaching the maximum where 10 m.e. of calcium was applied at a pH of 6.0 to 6.5.

Woodhouse (42) in North Carolina, concluded that the time and method of application of lime were more important than the rate of application. Best results were obtained by mixing the lime in the plow layer before planting. A high level of calcium depresses the uptake of magnesium and

potassium. It is typical of calcareous soil to require high levels of potassic fertilizers. This fact is well known on the thin chalk soils of southern and eastern England (32).

Alfalfa requires relatively large amounts of phosphorus. Only a part of the phosphorus fertilizer added to the soil as available phosphorus is used by the plant (25). Seay and Weeks (36), indicated that the best time for application of phosphate fertilizers was in the fall. They found that phosphorus was taken up by alfalfa during the dormant season. Nielson (30), indicated that the time of application of phosphate was not critical. Fall applications appeared to be equally as effective as spring applications. Woodhouse (43) found that young alfalfa plants have a high requirement for phosphorus.

Phosphate fertilizers on Washington soils were compared by Hausenbuiller and Weaver (14). They found that fertilizer phosphorus was neither leached from the soil nor reverted into an unavailable form. As a result, highly available phosphate carriers can be applied to alfalfa in amounts sufficiently large to last for several years.

Larson (17) found that yields of oats and alfalfa were markedly increased by phosphate fertilizer. The yields of the first two crops followed a curve of diminishing returns. Later, however, the first increment of 30 pounds of  $P_2O_5$  per acre became ineffective. The first two years of the experiment, a corresponding increase in phosphorus and magnesium uptake was observed with phosphate applications, while the total uptake of calcium decreased. Hunter (15) concluded that the level of available phosphate in the soil was the most important factor affecting the phosphorus content of alfalfa.

MacLean and Cook (20) studied the effect of soil reaction on phosphorus availability. They found that liming to slightly above the neutral point increased the amount of available soil phosphorus.

Millar (23) reported that over 80 percent of the phosphorus applied to American soils in fertilizers is in forms designated as available, and from 5 to 15 percent of it is recovered in the first crop harvested after the application. The loss of available phosphates is due to the reversion of phosphorus from a soluble form to an insoluble form known as fixation. Murphy (26) has shown that phosphate fixation may occur in soils high in kaolin clay minerals. He believed this probably accounts for the phosphate that is fixed at about neutrality. However, the fixation power of most clay minerals is relatively low.

Seay (37) found a linear relationship in Wisconsin soils existed between the percentage of potassium contained in alfalfa and the logarithm of the number of pounds of exchangeable potassium in the soil on which the crop was grown. Brown (5) studied potassium and boron fertilization of alfalfa on some Connecticut soils. He reported that large applications of  $K_2O$ , before planting, produced alfalfa with a high potassium and low calcium content the first year.

It is well known by soil chemists that certain cations may be sorbed by the clay minerals in a nonexchangeable or a difficultly exchangeable state. Potassium is the most common ion that is "fixed" to any appreciable degree (12). Nelson and McEvoy (29) showed that an increase in yield and quality of tobacco was received when  $MgO$  was added to the soils that had a sufficient supply of available  $K_2O$ .

Chandler et al. (7) found the potassium content of alfalfa to be a reliable criterion for predicting the need of potassium fertilization. When the potassium content of the alfalfa plant at early bloom stage was less than 1.25 percent a profitable yield response usually resulted from fertilizer applications. When potassium content was over 1.25 percent, there was seldom any response to potassium fertilization. These workers proposed the critical level of the soil to be 80 pounds of exchangeable potassium per acre. Murphy (27) found that soil containing less than 60 P.P.M. of replaceable potassium generally responded to potassium fertilization if other factors were favorable for plant growth. Bear and Toth (1) found that alfalfa plants had the tendency to take up excess potassium at the expense of magnesium when excessive applications of potassium were made.

In many instances the trace elements are the first limiting plant growth factor. Boron has received considerable study in soil fertility experiments with alfalfa (2). The concentration range between the minimum amounts for plant growth and those which are toxic is relatively narrow. Stinson (38) found that the total boron content of alfalfa varied directly with the water soluble boron of the soil. Dible and Berger (9) reported that the level indicating a boron deficiency was approximately 9 P.P.M. Brown and King (6) decreased boron deficiency symptoms, increased height by 15 percent and yield by 16 percent with the application of boron. Boron content of the leaves was increased by 21 to 62 percent with the application of 20 pounds of borax per acre as compared with alfalfa that was not fertilized with boron. Murphy and Lynd (28) found increases in

yield of alfalfa hay in southeastern Oklahoma with the application of 32, 64 and 96 pounds  $P_2O_5$  per acre. These phosphorus treatments combined with 72 pounds of  $K_2O$  gave larger increases over the respective  $P_2O_5$  treatments alone. The addition of 40 pounds borax to the 0-64-72 treatment resulted in the highest yields in the experiment.

Manganese deficiencies commonly occur on soils of high pH and of high organic matter content (10). Lynd and Turk (19) found that with increasing rates of lime there was a marked decrease in exchangeable manganese. Garey and Barber (10) found evidence that oxidation of forms of sulfur or acid production were important for manganese to become available from unavailable forms. Varva and Fredrick (40) found that oxidation of elemental sulfur or sodium-thiosulfate applied to the soil resulted in a release of soluble manganese accompanied by a lowering of pH.

Many cultivated plants need comparatively large amounts of sulfur. In a humid climate the soil loses much sulfur through leaching. Bear (2) reported a marked increase in yields of crops, especially legumes, has been obtained by applications of sulfur fertilizers in many areas of the United States. He also pointed out that rainfall delivers between 5 and 30 pounds of sulfur per acre annually in most areas.

### III MATERIALS AND METHODS

#### Field Experiments

A field experiment on a Port loam soil was located on the Thomas farm about  $2\frac{1}{2}$  miles east of Stillwater in Payne County, Oklahoma, near State Highway 51 in the  $NW\frac{1}{4}NW\frac{1}{4}$  sec. 20, Twp. 19 N., R. 3 E.

This soil was formed from material of alluvial origin and is located on an occasionally inundated floodplain. Port loam soil has a brown top soil about 16 inches in depth, which has a medium granular structure and friable consistence. It is underlain by calcareous, reddish-brown alluvial material. A detailed description of this soil series may be found in the Manual of Soil Series of Oklahoma (21). This field had been in continuous corn since 1948 and did not receive any lime during that period.

The plots on a Norge fine sandy loam soil were located on the Paradise farm, about 9 miles south and 7 miles west of Stillwater in Payne County, Oklahoma in the  $SE\frac{1}{4}SE\frac{1}{4}$  sec. 34, Twp. 18 N., R. 1 E.

This soil was formed from material of old alluvial origin. Norge has a brown sandy loam topsoil about 8 inches in depth which has a weak fine granular structure and friable consistence accompanied by a few fine pores. It grades gradually to the layer below. A detailed description of this soil may be obtained from the Manual of Soil Series

of Oklahoma (21).

Experiments were started on an established stand of alfalfa in February of 1955 at the Thomas farm and in March of 1956 at Paradise farm. The annual applications of the treatments used were applied in the spring of 1957. These treatments included annual applications of the following at the Thomas and Paradise farms.

P<sub>1</sub> = 40 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%)  
 P<sub>2</sub> = 80 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%)  
 K<sub>1</sub> = 100 pounds K<sub>2</sub>O per acre as KCl (60%)  
 K<sub>2</sub> = 200 pounds K<sub>2</sub>O per acre as KCl (60%)  
 B = 40 pounds borax per acre (11.3% boron)

In addition, the Paradise experiment was expanded, which permitted studies with increased rates of phosphorus.

P<sub>3</sub> = 120 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%)  
 P<sub>4</sub> = 160 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%)  
 P<sub>5</sub> = 200 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%)  
 K<sub>1</sub> = 100 pounds K<sub>2</sub>O per acre as KCl (60%)  
 K<sub>2</sub> = 200 pounds K<sub>2</sub>O per acre as KCl (60%)  
 B = 40 pounds borax per acre (11.3% boron)

These plots were laid out in a split plot arrangement in a randomized block having all possible combinations of the above treatments with three replications.

#### Greenhouse Experiment

The objective of the greenhouse experiment was to determine the effects of calcium and magnesium ratios with and without potassium and phosphorus, and a combination of these elements, on the yield of alfalfa grown on a Norge fine sandy loam soil.

This soil was selected because it is a deep, well drained, permeable soil that will give high alfalfa yields with proper fertility practices and favorable moisture.

The soil was collected from the field, screened through a  $\frac{1}{4}$ -inch mesh screen and air dried. The containers being used in this experiment were two gallon, glazed, earthenware pots. Nine kilograms of soil were weighed into a sufficient number of pots to enable all treatments to be made in triplicate. Each of the 36 treatments were replicated making a total of 108 pots. All pots were adjusted to the same level of nitrogen as that supplied in 200 pounds of monoammonium phosphate. Monoammonium phosphate was selected as the phosphorus carrier to eliminate the application of calcium. The treatments were designated as follows:

Check	P <sub>2</sub>	P <sub>2</sub> K <sub>1</sub>	K <sub>1</sub>	P <sub>1</sub>	P <sub>1</sub> K <sub>1</sub>
Ca <sub>4</sub>	Ca <sub>4</sub> P <sub>2</sub>	Ca <sub>4</sub> P <sub>2</sub> K <sub>1</sub>	Ca <sub>4</sub> K <sub>1</sub>	Ca <sub>4</sub> P <sub>1</sub>	Ca <sub>4</sub> P <sub>1</sub> K <sub>1</sub>
Mg <sub>4</sub>	Mg <sub>4</sub> P <sub>2</sub>	Mg <sub>4</sub> P <sub>2</sub> K <sub>1</sub>	Mg <sub>4</sub> K <sub>1</sub>	Mg <sub>4</sub> P <sub>1</sub>	Mg <sub>4</sub> P <sub>1</sub> K <sub>1</sub>
Ca <sub>3</sub> Mg <sub>1</sub>	Ca <sub>3</sub> Mg <sub>1</sub> P <sub>2</sub>	Ca <sub>3</sub> Mg <sub>1</sub> P <sub>2</sub> K <sub>1</sub>	Ca <sub>3</sub> Mg <sub>1</sub> K <sub>1</sub>	Ca <sub>3</sub> Mg <sub>1</sub> P <sub>1</sub>	Ca <sub>3</sub> Mg <sub>1</sub> P <sub>1</sub> K <sub>1</sub>
Ca <sub>2</sub> Mg <sub>2</sub>	Ca <sub>2</sub> Mg <sub>2</sub> P <sub>2</sub>	Ca <sub>2</sub> Mg <sub>2</sub> P <sub>2</sub> K <sub>1</sub>	Ca <sub>2</sub> Mg <sub>2</sub> K <sub>1</sub>	Ca <sub>2</sub> Mg <sub>2</sub> P <sub>1</sub>	Ca <sub>2</sub> Mg <sub>2</sub> P <sub>1</sub> K <sub>1</sub>
Ca <sub>1</sub> Mg <sub>3</sub>	Ca <sub>1</sub> Mg <sub>3</sub> P <sub>2</sub>	Ca <sub>1</sub> Mg <sub>3</sub> P <sub>2</sub> K <sub>1</sub>	Ca <sub>1</sub> Mg <sub>3</sub> K <sub>1</sub>	Ca <sub>1</sub> Mg <sub>3</sub> P <sub>1</sub>	Ca <sub>1</sub> Mg <sub>3</sub> P <sub>1</sub> K <sub>1</sub>

Ca <sub>4</sub>	= 10 ton CaCO <sub>3</sub> per acre (Tech.)
Mg <sub>4</sub>	= 8.4 ton MgCO <sub>3</sub> per acre (C.P.)
Ca <sub>3</sub> Mg <sub>1</sub>	= 7.5 ton CaCO <sub>3</sub> and 2.1 ton MgCO <sub>3</sub> per acre
Ca <sub>2</sub> Mg <sub>2</sub>	= 5.0 ton CaCO <sub>3</sub> and 4.2 ton MgCO <sub>3</sub> per acre
Ca <sub>1</sub> Mg <sub>3</sub>	= 2.5 ton CaCO <sub>3</sub> and 6.3 ton MgCO <sub>3</sub> per acre
K <sub>1</sub>	= 100 pounds K <sub>2</sub> O per acre as KCl (C.P.)
P <sub>1</sub>	= 100 pounds P <sub>2</sub> O <sub>5</sub> per acre as monoammonium phosphate (C.P.)
P <sub>2</sub>	= 200 pounds P <sub>2</sub> O <sub>5</sub> per acre as monoammonium phosphate (C.P.)

All treatments were mixed thoroughly with the upper three inches of the soil. The approximate moisture equivalent value was determined. On this basis the soil was watered to its approximate field capacity before planting. Certified Buffalo alfalfa, Medicago sativa, was planted

September 23, 1957. The seed was treated with an inoculum, Rhizobium species, before planting. The plantings were made in circular bands within each pot and covered to a depth of  $\frac{1}{2}$ -inch. Following emergence, the number of plants was adjusted to 10 per pot.

The first, second and third cuttings were harvested February 28, April 8 and May 1, 1958 respectively. The plant material was dried in the oven at 65°C. and weighed.

All alfalfa hay yields were subjected to statistical analyses to aid in interpreting these data.

Physical and chemical properties of the soils used in the field experiment and greenhouse experiment are reported in Tables I and II respectively. Available phosphorus was determined by leaching with 0.1 normal acetic acid as proposed by Harper (13). Exchange capacity and exchangeable potassium were determined by the procedure presented by Jackson (16). Total nitrogen was determined by modification of the Kjeldahl method (32). The percentage organic matter was determined by the procedure outlined by Schollenberger (35). Soil reaction was determined using the Beckman glass-electrode pH meter. Mechanical analyses were made by the hydrometer method essentially as presented by Bouyoucos (4).

#### IV RESULTS AND DISCUSSION

Greenhouse and field experiments were conducted to determine response of alfalfa to fertilization. Two soil types were studied in the field experiment, Port loam and Norge fine sandy loam, the latter was also used in the greenhouse experiment.

##### Field Experiment

Port loam: The 1957 growing season was very favorable for alfalfa production because of high rainfall. Four cuttings of hay were harvested. Total yields by cuttings with statistical results are summarized in Table III and the actual plot yields are shown in the appendix, Tables IX, X, XI and XII.

The maximum total yield of 11,289 pounds per acre was harvested from those plots receiving the  $P_1K_1E$  treatment. The lowest total mean yield of 9,358 pounds per acre was obtained from the  $P_2$  treatment. The average total yield from the check (no fertilizer) treatment was 9,582 pounds per acre which is slightly above the lowest yielding plots.

There were no statistically significant yield differences between the treatments in the first cutting as indicated by the  $F$  value. The  $F$  value for potassium rates was significant at the 5% level for the second cutting. The phosphorus and potassium rates were both

<sup>1/</sup> Yield figures are the mean of three replications.

<sup>2/</sup> Treatment symbols are:

Check = no fertilizer.

P<sub>1</sub> = 40 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%).

P<sub>2</sub> = 80 pounds P<sub>2</sub>O<sub>5</sub> per acre as treble superphosphate (45%).

K<sub>1</sub> = 100 pounds K<sub>2</sub>O per acre as KCl (60%).

K<sub>2</sub> = 200 pounds K<sub>2</sub>O per acre as KCl (60%).

B = 40 pounds borax per acre (11.3%).

<sup>3/</sup> \* = Significant at 5% level.

\*\* = Significant at 1% level.

n.s. = Not significant at 5% level.

significant at the 1% level in the third and fourth cuttings. The P x K interaction of the fourth cutting was significant at the 5% level.

Phosphorus treatments alone gave a slight decrease in yields as compared with the check (no fertilizer) treatment with a mean yield of 9,582 pounds per acre. The phosphorus treatments when in combination with the potassium treatments gave increases of more than a thousand pounds per acre in all cases over the check (no fertilizer) treatment.

When the effect of phosphorus and potassium treatments were combined with boron, yields in all cases were increased above those receiving phosphorus and potassium alone.

Potassium treatments indicated linear response in all combinations except the P<sub>2</sub>K<sub>1</sub>B treatment. The boron treatment gave a slight increase in yield over the no fertilizer treatment. Boron in combination with phosphorus and potassium also gave increased yields.

Norge fine sandy loam: Two experiments were conducted on this soil. Each experiment received the same rates of potassium and boron but had different rates of phosphorus applied. One area is referred to as the low phosphorus area, which had the check (no fertilizer) treatment and two phosphorus rates of 40 and 80 pounds P<sub>2</sub>O<sub>5</sub> per acre. The other area is referred to as the high phosphorus area and received 120, 160 and 200 pounds of P<sub>2</sub>O<sub>5</sub> per acre.

Four alfalfa hay cuttings and one seed crop were taken from this experiment in 1957.

The hay and seed yields for the low phosphate level with the statistical results are summarized in Tables IV and V respectively.

1/ See Table IV for details of treatments.

n.s. = Not significant at 5% level.

The hay and seed yields for the high phosphate levels with statistical results are summarized in Tables VI and VII. Actual plot yields of the low phosphate area are shown in appendix Tables XIII, XIV, XV and XVI with the actual plot yields from the high phosphate levels shown in appendix Tables XVII, XVIII, XIX and XX.

Low phosphate levels for alfalfa forage: Lowest total mean yield of alfalfa hay, 6,788 pounds per acre was obtained from the check (no fertilizer) treatment. Highest average total yield, 7,937 pounds per acre was obtained from the  $P_2K_1B$  treatment.

Statistically significant differences were obtained on the phosphorus level with the first cutting as indicated by the F value. There were no statistical differences between the treatments in the second cutting. The potassium treatments gave yields different significantly at the 1% level in the third cutting and yields from the phosphorus treatments were significantly different at the 1% level in the fourth cutting. The only significances in the average total yield was at the 5% level as a function of potassium treatment.

Low phosphate levels for seed: Yields of alfalfa seed from the field experimental plots that received the low phosphorus treatments are summarized in Table V. Lowest yields of 43.0 pounds per acre were obtained from the  $K_2$  treatments. The highest yields of 111.0 pounds per acre were obtained from the  $P_2K_2B$  treatments and the  $P_2K_1B$  treatments with an average yield of 110.7 pounds per acre.

The check (no fertilizer) treatments gave yields of 97.0 pounds per acre which was exceeded by only four treatments. These treatments

were  $P_2K_2B$ ,  $P_2K_1B$ ,  $P_1K_1$  and  $P_2K_1$ .

High phosphate levels for alfalfa forage: The lowest total yield, 5,702 pounds per acre was obtained from the  $P_3B$  treatments. Highest total yield, 6,908 pounds per acre was obtained from the  $P_3K_2B$  treatments.

Statistically significant differences were obtained at the 5% level for the first cutting on the P treatments and the P x K and K x B interactions with significance at the 1% level on the P x K x B interactions. The second cutting had no significance except at the 5% level on the P x K x B interactions. The third cutting showed no significant differences in yield with any treatment. Significance in yield difference was shown at the 5% level on the K treatment and at the 1% level on the P x K treatments for the fourth cutting. The only significant difference in the average total yield was at the 5% level on P x K treatments.

The phosphorus treatments alone appeared to give linear response. The  $P_3K_1$ ,  $P_3K_2$ ,  $P_4K_1$  and  $P_4K_2$  treatment combinations gave increased yields over the  $P_3$  and  $P_4$  treatments. However, the  $P_5K_1$  and  $P_5K_2$  treatments gave lower yield than  $P_5$  treatment alone. Increases were also noted for the boron treatments over the phosphorus alone and phosphorus and potassium combinations.

Seed yields for the high phosphorus levels: Yields of alfalfa seed from the field experimental plots that received the high phosphorus treatments are summarized in Table VII. Lowest yields of 55.6 pounds of seed per acre was obtained from the  $P_4$  treatments. The highest yield, 123.3 pounds of seed per acre was obtained from the  $P_5B$  plot treatments. Boron with three rates of phosphorus alone, gave higher yields than any of the

boron, phosphorus and potassium combinations. Potassium application at the  $K_2$  treatment level with three rates of phosphorus gave higher increases than the  $K_1$  treatment plus three rates of phosphorus. These data indicate the need for nutrient element balance for seed production with a high rate of fertilizer application.

#### Greenhouse Experiment

Norge fine sandy loam: Three cuttings of alfalfa forage were obtained from this experiment. Total yields and results of the statistical analysis by treatments are shown in Table VIII. Forage yields by cuttings with statistical analysis of yields are shown in appendix Table XXI.

The pots receiving the  $Mg_4K_1$  treatments produced the highest total yield, 13.52 grams. The lowest total yield of 10.26 grams per pot was obtained from the check treatments (no differential fertilization). An apparent linear type response was noted with decreasing amounts of calcium and increasing amounts of magnesium as indicated by the average of the calcium and magnesium treatments. Blalock (3) worked with alfalfa on a Waynesboro soil in the greenhouse. He found that plant growth was inhibited with the application of 8.4 tons of  $MgCO_3$  per acre. The 8.4 tons of  $MgCO_3$  per acre, on the Port loam soil gave the highest average yield of 12.91 grams which is higher than calcium alone or combined calcium and magnesium treatments.

The mean yield of the  $P_1K_1$  treatments with all combinations of calcium and magnesium was higher than the  $P_2K_1$  treatments with the same calcium and magnesium combinations.

The addition of phosphorus at both the  $P_1$  and  $P_2$  levels increased

1/ Soil fertility treatments were as follows:

Check = No differential fertility treatments.

Ca<sub>4</sub> = 10 ton CaCO<sub>3</sub> per acre (Tech.)

Mg<sub>4</sub> = 8.4 ton MgCO<sub>3</sub> per acre.

Ca<sub>3</sub>Mg<sub>1</sub> = 7.5 ton CaCO<sub>3</sub> and 2.1 ton MgCO<sub>3</sub> per acre.

Ca<sub>2</sub>Mg<sub>2</sub> = 5.0 ton CaCO<sub>3</sub> and 4.2 ton MgCO<sub>3</sub> per acre.

Ca<sub>1</sub>Mg<sub>3</sub> = 2.5 ton CaCO<sub>3</sub> and 6.3 ton MgCO<sub>3</sub> per acre.

K<sub>1</sub> = 100 pounds K<sub>2</sub>O per acre as KCl (C.P.)

P<sub>1</sub> = 100 pounds P<sub>2</sub>O<sub>5</sub> per acre as monoammonium phosphate.

P<sub>2</sub> = 200 pounds P<sub>2</sub>O<sub>5</sub> per acre as monoammonium phosphate.

All pots received CO(NH<sub>2</sub>)<sub>2</sub> in an amount to supply equivalent nitrogen supplied by 200 lbs./A of monoammonium phosphate.

2/ Yield figures represent the mean of three replicate pots.

\* Significant at 5% level.

the total average yield over the check. It was also noted that when potassium was applied, the total average yield exceeded the check. The check,  $K_1$  and  $P_2K_1$ , gave average total yields less than the overall mean of 12.03 grams per pot.

## V SUMMARY AND CONCLUSIONS

The objective of the field and greenhouse experiment was to determine the differential response of alfalfa seed and forage yield to various soil fertility treatments. Field experiments were conducted at two locations near Stillwater, Oklahoma, on Port loam and Norge fine sandy loam. A greenhouse study was conducted using a Norge fine sandy loam soil.

The field experimental studies included different rates of phosphorus and potassium fertilization with and without boron. Four alfalfa hay cuttings were obtained from both field experiments.

Field experimental results indicated the following:

1. Alfalfa yields were significantly increased by potassium fertilization on all but one cutting on the Port loam soil.
2. Yield increases were obtained with the application of boron with the highest yield obtained from the application of 40 pounds of borax per acre in combination with 40 pounds  $P_2O_5$  and 100 pounds  $K_2O$  per acre on the Port loam soil.
3. The mean total yields of alfalfa forage from all cuttings were significantly increased with potassium fertilization in combination with the low phosphate treatments on the Norge fine sandy loam soil.

4. The highest average total yield was obtained from the treatment combinations of 100 pounds  $K_2O$ , 80 pounds  $P_2O_5$  and 40 pounds borax applied per acre on the Norge fine sandy loam soil from the low phosphate level experiment.

5. Differences in the average seed yields were not significantly affected by soil fertility treatments at the 5% level. The highest average alfalfa seed yield was obtained from 80 pounds  $P_2O_5$ , 200 pounds  $K_2O$  and 40 pounds borax applied per acre with the low phosphate treatments on the Norge fine sandy loam.

6. Significance was found for the P x K interaction on the average total yield of alfalfa forage in the high phosphate rate experiment. Differences between average yields of alfalfa hay as affected by various soil fertility treatments were not significant at the 5% level with the high phosphate fertilization treatments. Highest average yields were obtained from 120 pounds  $P_2O_5$ , 200 pounds  $K_2O$  and 40 pounds borax per acre with the high phosphate fertilization experiment on the Norge fine sandy loam soil.

7. Boron and phosphorus combinations gave higher alfalfa seed yields than did boron, phosphorus and potassium combinations on the Norge fine sandy loam soil, with the higher phosphate levels.

The greenhouse experiment was conducted to determine the effects of calcium and magnesium ratios with and without potassium and phosphorus fertilization on yield of alfalfa forage. Three cuttings were obtained from this experiment.

Greenhouse experimental results are summarized as follows:

1. A linear type increase in alfalfa yield was indicated on the Norge fine sandy loam with increasing amounts of magnesium, up to 8.4 tons  $MgCO_3$  per acre combined with decreasing amounts of calcium. Alfalfa yields were significantly affected by fertility treatments. The highest average total yield was obtained from the 8.4 ton of  $MgCO_3$  and 100 pounds  $K_2O$  per acre treatment.

2. No consistent yield response to the three different rates of phosphorus and two rates of potassium fertilization alone and in combination was apparent with the various calcium and magnesium treatments applied to the Norge fine sandy loam soil.

Sm = .179		Treatment F = 1.52 n.s.			C. V. = 21.30%		

1/ See Table VIII for details of treatments.

2/ Yield figures represent the mean of three replicate pots.

n.s. = Not significant at 5% level.

\*\* = Significant at 1% level.

VITA

Billy Bob Burris

Candidate for the Degree of

Master of Science

Thesis: EFFECTS OF VARIOUS SOIL FERTILITY TREATMENTS ON ALFALFA HAY  
AND SEED YIELDS

Major: Soils

Biographical:

Personal data: Born July 31, 1934 at Yukon, Oklahoma, son of  
Ben F. and Ruby E. Burris.

Education: Attended elementary school at Yukon, Oklahoma;  
received a high school diploma at Yukon High School,  
Yukon, Oklahoma, 1954; undergraduate work at Oklahoma  
State University, 1954-1957; graduate work at Oklahoma  
State University, 1957-1958.

Experience: Reared on and operated a farm; graduate assis-  
tant, Oklahoma State University, 1957-1958.

Member: Agronomy Club, Soil Conservation Society of America  
and Dairy Science Club.

Date of Final Examination: August, 1958.

THESIS TITLE: EFFECTS OF VARIOUS SOIL FERTILITY TREATMENTS ON ALFALFA  
HAY AND SEED YIELDS

AUTHOR: Billy Bob Burris

THESIS ADVISER: Dr. J. Q. Lynd
