## Acknowledgements

My first and foremost thanks and appreciation to Dr. Qi Cheng for persevering with me as my advisor throughout the time it took me to complete this research. He has provided guidance, support, ideas, and encouragement during my time at the University of Oklahoma. This dissertation would never be finished without him.

I appreciate my committee members, Dr. Sudarshan Dhall, Dr. Changwook Kim, Dr. Ralf Schmidt, and Dr. Krishnaiyan Thulasiraman, for their precious time and effort to read this dissertation and give their suggestions.

Many thanks to Jim Summers for his excellent server administration. This dissertation contains a large amount of computation on CS lab servers. Without sound working Linux machines, data generation would have difficulties.

I want to thank Barbara Bledsoe and Chyrl Yerdon for office support, for assisting with course enrollment, and for all sorts of tedious paper work. My special thanks to Barbara for her always kind, efficient, and helpful responses to me and everybody.

Last but definitely not the least, I would like to thank my wife, Chia-Hui Tsai, for her support and encouragement. I could not have completed this effort without her assistance, tolerance, and enthusiasm.

#### Abstract

The problem size gets larger as computers become faster. Using naive algorithms, even equipped with fast CPUs and large memories, computers still cannot handle many problems of certain size. Some searching tasks, however, can be answered with the help of the algorithmic technique, such as time and space trade-off.

Let $k$ and $n$ be positive integers, $n>k$. Define $r(n, k)$ to be the minimum positive value of $$
\left|\sqrt{a_{1}}+\cdots+\sqrt{a_{k}}-\sqrt{b_{1}}-\cdots-\sqrt{b_{k}}\right|
$$ where $a_{1}, a_{2}, \cdots, a_{k}, b_{1}, b_{2}, \cdots, b_{k}$ are positive integers no larger than $n$. It is important to find a tight bound for $r(n, k)$, in connection to the sum-of-square-roots problem, a famous open problem in computational geometry. The current best lower bound and upper bound are far apart. For exact values of $r(n, k)$, only a few simple cases have been reported so far, and they can be found easily using exhaustive search. A new algorithm is developed to find $r(n, k)$ exactly in $n^{k+o(k)}$ time and in $n^{\lceil k / 2\rceil+o(k)}$ space. Space usage is decreased dramatically along with little increase in time, compared to an intuitive trade-off method. Our algorithm reduces time for swap-in and swap-out, minimizing the total running time. The problem is solved in size that was infeasible for a naive trade-off scheme. We also present lots of numerical data.

The time and space trade-off technique has its limitation. For some problems, when space is reduced to a certain extent, time will be increased exponentially. The trade-off technique does not apply to this situation. We explore such a property that discourages trade-off attacks.

Key generation is an important part of symmetric-key encryption algorithms, such
as AES. A key derivation function can be used to generate symmetric cipher session keys. As CPU technology advances, key derivation functions are more vulnerable to off-line brute force attacks. Based on the Memory Wall problem, we propose a simple number-theoretic way to mitigate exhaustive search attacks. We also present a formal definition of memory-bounded functions. On one hand, if attackers try to reduce memory usage, they are forced to spend dramatically more time. On the other hand, a memory-bound security scheme will minimize the difference between high-end and low-end computers. Trade-off attacks will hence be deterred.

## Chapter 1

## Introduction

Two important parts of a digital computer are central processing unit (CPU) and memory. The CPU reads data from memory, executes instructions, and stores results back to memory. Computers solve problems due to their CPU power and memory. The computation power is evaluated in cycles per unit time. A faster computer can run more cycles in the same amount of time and results in less CPU time. Memory as a storage space can be classified by accessing speed. Faster memory is costlier and hence smaller in capacity. With the advance of computer hardware technology, computers are capable of solving more complex problems than before.

To quote a Chinese proverb "While the priest climbs a post, the devil climbs ten". Problem size gets larger as computers become faster. Using naive algorithms, even equipped with fast CPUs and large memories, computers still cannot handle many problems of certain size. Some problems, however, can be answered with the help of algorithmic techniques.

Many exhaustive searching tasks, such as inversion of one-way functions and discrete logarithm problems, allow time-space trade-offs Hellman80. Time and space trade-off is an algorithmic technique to accelerate CPU throughput. Time refers to CPU time while space can be cache, memory, or hard drive. In this dissertation, space refers to main memory and will be used interchangeably. The key idea of trade-off schemes is reusability of one-time work: compute once and reuse again. From computational point of view, time can be saved by reusing pre-computed results stored in some space. As long as storage-lookup time is less than re-computation time, this
technique would be effective. Time and space trade-off is financially worthy. The cost to update a CPU is usually more expensive than to expand storage space. The advance of CPU technology is also faster than that of storage. The trade-off technique is a good choice when the budget to improve computer performance is limited.

### 1.1 Time and space trade-off

An example of time and space trade-off is to invert a one-way string permutation $f$, where sometimes exhaustive search is the only choice. Given a string $y$, we look for $f^{-1}(y)$ from $N$ possible permutations such that $f\left(f^{-1}(y)\right)=y$. Let $M$ be the total space and $T$ be the total time required to derive an answer. We assume that storing a string needs $M=1$ and that computing $f$ once takes $T=1$. One intuitive way, completely relying on CPU computations, costs $M=1$ and $T=N$, resulting in minimum memory demand but slow speed. Another extreme way needs $M=N$ but is fast. It is composed of two phases, preprocessing (off-line) and on-line phase. The off-line phase stores all pairs of $y$ and $f^{-1}(y)$ in a sorted table while the on-line phase answers by a lookup. The scheme depends absolutely on memory and costs $T=\log N$ and $M=N$. Although preprocessing time can be amortized by future searches, this extreme method consumes enormous space.

Hellman introduced a method to trade memory against time Hellman80. It is a middle ground between two extremes and is formed by preprocessing and on-line phases. Consider that each string is a point in a set of $N$ permutations. The idea is to divide $N$ by $m$, the number of chains, as shown in Figure 1.1. For each starting point, permute repeatedly $t$ times to derive an endpoint. One endpoint takes $t$ operations and hence $m$ endpoints would cover all $N$ points. To build a lookup table, the space requirement is $2 m$, storing only pairs of starting and ending points. The preprocessing phase constructs such a table and sorts it by ending points. The time requirement
is still $t m=N$, apparently not a good method for a one-time-only inversion. The preprocessing time can be, however, amortized over the number of inversions, if the task needs to be conducted more than once. The on-line phase aims to match $y$ in the sorted table. If $y$ is not found, the user has to permute $y$ and search for the new string; repeat till a match is found. When found, $f^{-1}(y)$ can be deduced by re-calculating the chain from the corresponding starting point. The on-line phase requires $T=t * \log (m)=\frac{N}{m} * \log (m)$ and $M=2 m$. The trade-off exists between $T$ and $M$.

Naively applying the technique will not benefit us much. Space requirement would still be huge for certain problems, such as finding the smallest gap between sums of square roots. The plain trade-off scheme works for certain problem sizes if space demands are feasible. For larger sizes, a better technique is expected.

### 1.2 The smallest gap between sums of square roots

Comparing the lengths of two polygonal paths can be treated as calculating the difference of the sums of square roots, as nodes are on integral coordinates in a two-

Figure 1.1: Hellman's cryptanalytic time-space trade-off
dimensional plane. The minimum nonzero difference has been an open problem for decades.

An efficient algorithm is developed to search for the minimum difference between the sums of square roots of small integers. As a typical searching task, the time and space trade-off technique is employed to save computation time. Our technique further improves the naive trade-off scheme. Space usage is decreased dramatically along with little increase in time, compared to an intuitive way. Our technique reduces time for swap-in and swap-out, minimizing the total running time. The problem is solved for sizes infeasible for the naive trade-off scheme.

### 1.3 Memory-bounded moderately hard functions

Slow computation, as an access-control mechanism, is preferred in some situations. It hinders a large surge of using certain computer resources, e.g. impediment to denial of service (DoS) attacks. DoS attack floods a network service with requests in a short time preventing legitimate users from the service. Examples of attacks include TCP SYN flooding and HTTP request flooding [JKR02. The idea is to take advantage of fast and free computing resources. Most network services rely on these characteristics

Figure 1.2: The minimum nonzero difference between two paths
to attract customers. Malicious users exploit properties to obstruct traffic.
Some problems can be solved in polynomial time. They are considered easy problems. There exist situations when space is reduced to certain extent, time will be increased exponentially. Easy problems become hard ones. The trade-off technique does not apply to them. We want to explore such property that discourages trade-off attacks.

The anti-tradeoff property provides a solution against DoS attacks. Forcing to walk randomly in certain amount of memory is a good access-control mechanism. On one hand, it will be hard to attack. Trying to reduce memory amount usage, malicious users result in dramatically paying more time instead. This is a direction for security schemes. On the other hand, memory-bound control schemes will minimize differences between high-end and low-end computers.

### 1.4 Results and structure

The sum-of-square-roots problem is a famous open problem in computational geometry. The best lower bound and upper bound are far apart. Chapter 2 introduces a new upper bound. An algorithm in Chapter 3 finds exactly the minimum gap for small integers. The result has been published in the proceeding of the 9th Latin American Theoretical Informatics Symposium (LATIN 2010) CL10.

Memory-bounded functions have been designed to combat email spams in a sequence of papers ABMW03, DGN03, DNW05] but lacked for a formal definition. The first formal definition is given in Chapter 4. A number-theoretic construction is in Chapter 5. The result has been published in the International Symposium on Trusted Computing [CL08]. Conclusion and future work will be discussed in Chapter 6 .

## Chapter 2

## Sums of Square Roots

### 2.1 Introduction

In computational geometry, a fundamental problem is to compare lengths of two polygonal paths. On a two-dimensional plane, if points have integer coordinates, the length of a line can be expressed in a square root of an integer because of the Pythagorean Theorem. Several connected such lines form a polygonal path. The length of a path can be expressed in the sum of square roots of integer. Given two paths, we want to know their difference to determine a shorter one.

The problem of comparing two sums of square roots of integer exists in Turing Machine model. Computational geometry relies on computers. Computers nowadays are an implementation of the Turing machine model. Compared to the real-number model, Turing machine has its own limitation to handle this problem. In computational geometry one sometimes assumes a model of real-number machines, where one memory cell can hold one real number. It is then assumed that an algebraic operation, taking a square root as well as a comparison between real numbers can be done in one operation. There is a straight forward way to compare sums of square roots in a real-number machine. But this model is not realistic, as shown in Shamir79, Schonhage79.

The geometrical question can be reduced to a numerical problem of comparing two sums of square roots of integers.

Definition 2.1.1. For positive integers $n, k, a_{i}, b_{i}$. Let

$$
r(n, k) \stackrel{\text { def }}{=} \min _{1 \leq a_{i}, b_{i} \leq n}\left(\left|\sum_{i=0}^{k-1} \sqrt{a_{i}}-\sum_{i=0}^{k-1} \sqrt{b_{i}}\right|\right) \neq 0 .
$$

$r(n, k)$ describes the smallest gap between two sums while $-\log r(n, k)$ represents the number of digits of precision needed. We try to find an upper bound of $-\log r(n, k)$ as a function of $n$ and $k$. This has been an open problem for decades. The origin of it can be dated back to 1981 [O'Rourke81], or even earlier. So far, only weak bounds have been found [DMO01.

### 2.2 Related work

Angluin and Eisenstat AE04 considered the case $k=2$ and gave bounds on the minimum nonzero separation of the sum of two square roots of positive integers from an integer. They proved that $r(n, 2)=\Theta\left(\frac{1}{n^{3 / 2}}\right)$.

Using the root separation method, Burnikel et al. BFMS00] proved that $-\log r(n, k)=$ $O\left(2^{2 k} \log n\right)$.

The Prouhet-Tarry-Escott problem asks for two disjoint sets $A$ and $B$ of $n$ integers each, such that: $\sum_{a \in A} a^{i}=\sum_{b \in B} b^{i}$ for each integer i from 1 to a given k. For a fixed $k, \Omega\left(k \log n-\frac{1}{2} \log n\right)$ is a lower bound of $-\log r(n, k)$ due to Ronald Graham QW06.

Qian and Wang QW06 gave a constructive upper bound of $r(n, k)=O\left(n^{-2 k+\frac{3}{2}}\right)$, which is a lower bound of $-\log r(n, k)=\Omega(k \log n)$. They also conjectured that $\log r(n, k)=\Theta\left(n^{\frac{1}{2}-2^{k-2}}\right)$.

Cheng Cheng06 gave an upper bound $-\log r(n, k)=2^{O(n / \log n)}$ which beats the root separation bound as long as $n \leq c k \log k$ for some constant $c$.

There is a wide gap between the known upper bound and the lower bound of
$-\log r(n, k)$. Until the fundamental problem has been resolved, we cannot even put the presumably easy problem such as Euclidean Minimum Spanning Tree problem in $\mathbf{P}$ (the polynomial-time class), and the Euclidean Traveling Salesman problem in NP (the nondeterministic polynomial-time class).

### 2.3 An upper bound of the smallest gap

Qian-Wang's upper bound was derived from the inequality:

$$
0<\left|\sum_{i=0}^{2 k-1}\binom{2 k-1}{i}(-1)^{i} \sqrt{t+i}\right| \leq \frac{1 \times 3 \times 5 \times \cdots \times(4 k-5)}{2^{2 k-1} t^{2 k-\frac{3}{2}}}
$$

Let $a_{i}=\binom{2 k-1}{2 i-2}^{2}(t+2 i-2)$ for $1 \leq i \leq k$ and $b_{i}=\binom{2 k-1}{2 i-1}^{2}(t+2 i-1)$ for $1 \leq i \leq k$. Then we have

$$
0<\left|\sum_{i=1}^{k} \sqrt{a_{i}}-\sum_{i=1}^{k} \sqrt{b_{i}}\right| \leq \frac{1 \times 3 \times 5 \times \cdots \times(4 k-5)}{2^{2 k-1} t^{2 k-\frac{3}{2}}}
$$

Note that $\binom{2 k-1}{i}$ can be as large as $\binom{2 k-1}{k} \geq 2^{2 k-1} /(2 k)$. To get an upper bound for $r(n, k)$, assign

$$
n=\binom{2 k-1}{k}^{2}(t+k)
$$

thus we have $-\log r(n, k) \geq 2 k \log n-8 k^{2}+O(\log n+k \log k)$. Hence Qian and Wang's result only applies when $n$ is much greater than $2^{4 k}$. In particular it does not give a meaningful bound for small $n$ and small $k$, for instance, $r(100,7)$.

Another interesting upper bound depends on the Prouhet-Tarry-Escott problem, which is to find a solution for a system of equations:

$$
\sum_{i=1}^{k} a_{i}^{t}=\sum_{i=1}^{k} b_{i}^{t}, \quad 1 \leq t \leq k-1
$$

under the condition that $a_{1} \leq a_{2} \cdots \leq a_{k}$ and $b_{1} \leq b_{2} \cdots \leq b_{k}$ are distinct lists
of integers. No such solutions have, however, been found for $k=11$ and $k>13$ [BLP03]. Therefore the approach based on the Prouhet-Tarry-Escott problem is not scalable.

Here we present an upper bound based on the pigeonhole argument.

Definition 2.3.1. An integer $n$ is square-free if there is no integer $a>1$ such that $a^{2} \mid n$. We use $s(n)$ to denote the number of positive square-free integers less than $n$, e.g. $s(100)=61$.

Proposition 2.3.2. The set $\{\sqrt{n} \mid n \in \mathbb{N}$ is square-free $\}$ is linearly independent over rationals.

Proof. See A.0.4.

Theorem 2.3.3. We have

$$
r(n, k) \leq \frac{k \sqrt{n}-k}{\binom{s(n)+k-1}{k}-1}
$$

Proof. Consider the set $\left\{\left(a_{1}, a_{2}, \cdots, a_{k}\right) \mid a_{i}\right.$ is squaer-free, $1 \leq a_{1} \leq a_{2} \leq \cdots \leq a_{k} \leq$ $n$. $\}$ The set has cardinality $(\underset{k}{s(n)+k-1})$. For each element $\left(a_{1}, a_{2}, \cdots, a_{k}\right)$ in the set, the sum $\sum_{i=1}^{k} \sqrt{a_{i}}$ is distinct by Proposition 2.3.2. Hence there are $\binom{s(n)+k-1}{k}$ many distinct sums in the range $[k, k \sqrt{n}]$. There must be two points within the distance $\frac{k \sqrt{n}-k}{\binom{s(n)+k-1}{k}-1}$ from each other. The theorem follows.

From this, one can derive

Corollary 2.3.4. $-\log r(n, k) \geq k \log n-k \log k+O(\log (n k))$

Note that in comparison to the Qian-Wang's bound, this is weaker when $n$ is very large. But it is better when $n$ is a polynomial in $k$. Hence, it has wider applicability. For example, when $n=100$ and $k=7$, it can give us a meaningful upper bound: $r(100,7) \leq 7.2 \times 10^{-8}$.

## Chapter 3

## The Smallest Gap Between Sums of Square Roots of Small Integers

### 3.1 Motivation

How close is the bound to reality? We need a provable bound which represent the actual situation. The bound should be as tight as possible. A way to show this is by running some feasible cases. In addition, numerical data shed lights on the type of integers whose square roots summations are extremely close.

So far only a few toy examples have been reported and they can be found easily using an exhaustive search:

$$
\begin{gathered}
r(20,2) \approx .0002=\sqrt{10}+\sqrt{11}-\sqrt{5}-\sqrt{18} \\
r(20,3) \approx .000005=\sqrt{5}+\sqrt{6}+\sqrt{18}-\sqrt{4}-\sqrt{12}-\sqrt{12}
\end{gathered}
$$

Computing power has gradually increased every year which allows us to go beyond toy examples. Nevertheless, it still has its limitation. Our extensive numerical studies cover only small $n$ and $k$.

In many practical situations, especially in the exact geometric computation, $n$ and $k$ are small. Explicit bounds like one we produce here help to decide how much precision is needed.

Moreover, since the upper bound is so far away from the lower bound, the numerical data may provide us some hints on which bound is closer to the truth and may
inspire us to formulate a reasonable conjecture on a tight bound of $r(n, k)$.

### 3.2 Space efficient technique

We are looking for the smallest difference between any two sums of square roots of integers by running cases on small $n$ and $k$. To the best of our knowledge, there is no better way other than exhaustive search.

The smallest non-zero difference only is due to two consecutive sums. Let $S$ be a set of sums of all combinations in form $\sqrt{a_{1}}+\sqrt{a_{2}}+\sqrt{a_{3}}+\cdots+\sqrt{a_{k}}$, where $1 \leq a_{i} \leq n$. For a given sum $s_{i} \in S$, the smallest difference of $\left|s_{i}-s_{j}\right|$ occurs when $|i-j|=1$, where $i, j$ are indices of sorted $S$. Otherwise, there will always be a smaller one. Hence the first task is to sort the sums of all combinations.

In terms of combinations, we need to enumerate all combinations with repetition. For example, for $n=2$ and $k=3$, we have $\{\sqrt{1}+\sqrt{1}+\sqrt{1}, \sqrt{1}+\sqrt{1}+\sqrt{2}, \sqrt{1}+$ $\sqrt{2}+\sqrt{2}, \sqrt{2}+\sqrt{2}+\sqrt{2}\}$. According to Euler, the number of $k$-combinations, with repetitions, from $n$ distinct object is

$$
|(n, k)|=\frac{(n+k-1)!}{k!(n-1)!}=\binom{n+k-1}{k} .
$$

The storage of all combinations takes up lots of memory space. A primitive double data type, which takes up 8 bytes, does not have enough precision. Instead, we use double-double QD08, which has approximately 32 decimal digits and requires 16 bytes. A middle-to-high end computer nowadays has memory about 8 gigabytes. To handle the case $(n, k)=(100,7)$, we need 45.4 gigabytes of memory space. It is prohibitive to handle such cases without a space-efficient algorithm.

Number theorists have been using a space-saving mechanism to test difficult conjectures on computers. For example, consider the following diophantine equation: $a^{4}+b^{4}+c^{4}=d^{4}$. Bernstein's idea Bernstein01] was to build two streams of sorted
integers, one for $a^{4}+b^{4}$ and another one for $d^{4}-c^{4}$, and then look for collisions. Algorithm 1 presents the mechanism. With this idea, the space requirement can be saved by $|S|^{\frac{1}{2}}$.

```
Algorithm 3.1: The space-saving mechanism for enumeration
    Input: \(P\) is a sorted list of \(\left|\left(n, k-\left\lceil\frac{k}{2}\right\rceil\right)\right|\) elements.
                \(Q\) is a sorted list of \(\left|\left(n, k-\left\lfloor\frac{k}{2}\right\rfloor\right)\right|\) elements.
    Output: The sorted list of \(|(n, k)|\) elements.
    Build a heap for \(P[i] \| Q[1], 1 \leq i \leq \operatorname{sizeof}(P)\);
    while \(\operatorname{sizeof}(P) \neq 0\) do
        Pop the root element, \(P[i] \| Q[j]\), from heap;
        if \(j<\operatorname{sizeof}(Q)\) then
            Push \(P[i] \| Q[j+1]\) into heap;
        end
        Re-heap;
    end
```

The use of heaps to enumerate the sums in a sorted order appeared quite early Knuth73, Section 5.2.3]. Let $P$ and $Q$ be sorted lists and let $P[i], Q[i]$ be the their $i$ th element, respectively. Denote element concatenation by $\|$. The above algorithm dynamically enumerates one element per iteration in sorted order, avoiding massive storage requirement. This is an important technique to perform exhaustive search beyond toy examples.

### 3.3 Algorithm for finding the gap

We present Algorithm 2 to compute $r(n, k)$ exactly based on the idea of enumerating summations using a heap. It further improves the execution performance: instead of $P[i] \| Q[j+1]$, Algorithm 2 pushes $P[i] \| Q\left[j^{\prime}\right]$ into the heap.

Theorem 3.3.1. When Algorithm 2 halts, it outputs $r(n, k)$.

```
Algorithm 3.2: Algorithm for finding \(r(n, k)\)
    Input: Two positive integers \(n, k(n>k)\).
    Output: \(r(n, k)=\) smallestDifference.
    Let \(P\) be an array containing all \(k\)-combinations, with repetitions, from 1 to \(n\).
    Let \(\left(a_{1}, a_{2}, \ldots, a_{A}\right)\) be an element in \(P\), where \(1 \leq a_{1} \leq a_{2} \leq \cdots \leq a_{A} \leq n\) and
    \(A=\left\lfloor\frac{k}{2}\right\rfloor\);
    Sort \(P\) according to \(\sum_{i=1}^{A} \sqrt{a_{i}}\);
    3 Let \(Q\) be an array containing all \((k-A)\)-combinations, with repetitions, from
    1 to \(n\). Let \(\left(a_{1}, a_{2}, \ldots, a_{k-A}\right)\) be an element in \(Q\), where
    \(1 \leq a_{1} \leq a_{2} \leq \cdots \leq a_{k-A} \leq n ;\)
    Sort \(Q\) according to \(\sum_{i=1}^{k-A} \sqrt{a_{i}}\);
    smallestDifference \(\leftarrow \infty\);
    previousRootValue \(\leftarrow 0\);
    Denote element concatenation by \(\|\). Build a heap for \(P[i] \| Q[1]\) according to
    \(\sum_{l=1}^{A} \sqrt{P[i][l]}+\sum_{l=1}^{k-A} \sqrt{Q[j][l]}\), where \(1 \leq i \leq \operatorname{sizeof}(P)\) and
    \(1 \leq j \leq \operatorname{sizeof}(Q)\).;
    while \(\operatorname{sizeo} f(P) \neq 0\) do
        Pop the root element, \(P[i] \| Q[j]\), from heap;
        currentRootValue \(\leftarrow \sum_{l=1}^{A} \sqrt{P[i][l]}+\sum_{l=1}^{k-A} \sqrt{Q[j][l]}\);
        if \(0<\mid\) currentRootValue - previousRootValue \(\mid<\) smallestDifference then
            smallestDifference \(\leftarrow \mid\) currentRootValue - previousRootValue|;
        end
        previousRootValue \(\leftarrow\) currentRootValue;
        if \(\exists j<j^{\prime}<\operatorname{sizeo} f(Q)\) such that \(P[i][A] \leq Q\left[j^{\prime}\right][1]\) then
            Push \(P[i] \| Q\left[j^{\prime}\right]\) into heap;
        end
        Re-heap;
    end
```

Proof. For any $1 \leq a_{1} \leq a_{2} \cdots \leq a_{A} \leq n$, define

$$
S_{a_{1}, a_{2}, \cdots, a_{A}}=\left\{\left(a_{1}, a_{2}, \cdots, a_{k}\right) \mid a_{A} \leq a_{A+1} \leq a_{A+2} \leq \cdots \leq a_{k} \leq n\right\}
$$

Partition the set $S=\left\{\left(a_{1}, a_{2}, \cdots, a_{k}\right) \mid 1 \leq a_{1} \leq a_{2} \leq \cdots \leq a_{k} \leq n\right\}$ into subsets according to the first $A$ elements, namely,

$$
S=\bigcup_{1 \leq a_{1} \leq a_{2} \leq \cdots \leq a_{A} \leq n} S_{a_{1}, a_{2}, \cdots, a_{A}} .
$$

As usual, we order two lists of integers by their sums of square roots. Consider the following procedure: select the smallest element among all the the minimum elements in all the subsets, and remove it from the subset. If we repeat the procedure, we generate a stream of elements of $S$ in a sorted order.

It can be verified that in our algorithm, the heap consists of exactly all the minimum elements from all the subsets. The root of the heap contains the minimum element of the heap. After we remove the element at the root, we put the next element from its subset into the heap. Hence the algorithm produces a stream of elements from $S$ in a sorted order. The minimum gap between two consecutive elements in the stream is $r(n, k)$ by definition.

Our search reveals that $r(100,8)=2.77 \times 10^{-21}$, which is reached by $\sqrt{16}+\sqrt{43}+$ $\sqrt{43}+\sqrt{46}+\sqrt{60}+\sqrt{85}+\sqrt{89}+\sqrt{95}$, which is 60.04349365830255824227265498 and $\sqrt{7}+\sqrt{41}+\sqrt{42}+\sqrt{51}+\sqrt{76}+\sqrt{83}+\sqrt{94}+\sqrt{97}$, which is 60.04349365830255824226988331 .

### 3.4 Time and space complexity

Without using Algorithm 1, a naive exhaustive search algorithm needs $O\left(n^{k}\right)$ space. Our means aims at the smallest difference. Once a new element is enumerated, the gap will be recorded, then the element can be freed.

Our algorithm uses much lesser space than the sorting approach while preserving the time complexity, which makes computing $r(100,8)$ feasible.

Theorem 3.4.1. The algorithm runs in time at most $n^{k+o(k)}$ and space at most $n^{\left\lceil\frac{k}{2}\right\rceil+o(k)}$.

Proof. Using the root separation bound, we need at most $O\left(2^{2 k} \log n\right)$ bit to represent the sum of square roots for comparison purposes. So comparing two elements takes time $\left(2^{2 k} \log n\right)^{O(1)}$. Since every element in $S$ appears at the root of the heap at most once and $|S| \leq n^{k}$, the main loop has at most $n^{k}$ iterations. For each iteration, the time complexity is

$$
\left(2^{2 k} \log n\right)^{O(1)} \log \left(n^{\left\lceil\frac{k}{2}\right\rceil}\right) .
$$

The complexity of other steps are much smaller comparing to the loop. Hence the time complexity is $n^{k+o(k)}$. The space complexity is clearly $n^{\left[\frac{k}{2}\right\rceil+o(k)}$.

### 3.5 Numerical data and observations

To implement our algorithm, the main issue is to decide the precision when computing the square roots and their summations. We need to pay attention to two possibilities: First, two summations may be different, but if the precision is set too small, then they appear to be equal numerically. Keep in mind that we have not ruled out that $r(n, k)$ can be as small as $n^{-2^{k}}$. Secondly two expressions may represent the same real number, but after the numerical calculation, they are different. This is the issue of numerical stability. In either case, we may get a wrong $r(n, k)$.

Our strategy is to set the precision at about $2 k \log n$ decimal digits. For example, to compute $r(100,8)$, we use the data type which has precision about 28 decimal digits. Whenever the difference of two summations is smaller than $n^{-2 k}$, we call a procedure based on Proposition 2.3.2 to decide whether the two numbers are equal or not.

We produce some statistical data about the sums of square roots and the gaps between two consecutive sums. On the same high-end PC, the computation takes about 18 hours to find $r(100,7)$ and about 30 days for $r(100,8)$. There are $217,538,310,639$ numbers in $[8,100]$ which can be written as summations of 8 square roots of positive integers less than 100. Hence there are 217, 538, 310, 638 gaps between two consecutive numbers after we sort all the sums.

In Table B. 6 and Figure B.6, we list an integer $8 \leq a \leq 80$ with the number of $\alpha$ such that $\lfloor\alpha\rfloor=a$ and $\alpha$ can be represented as $\sqrt{a_{1}}+\sqrt{a_{2}}+\cdots+\sqrt{a_{8}}$ ( $\left.1 \leq a_{1} \leq a_{2} \cdots \leq a_{8} \leq 100\right)$. Note that if two summations have the same value, they are counted only once. From the table, we see that there are $13,281,868,775$ sums in the $[55,56$ ), which gives us a more precise pigeonhole upper bound for $r(n, k)$ at $1 / 13281868775=7.529 \times 10^{-11}$, which is still several magnitudes away from $r(n, k)$.

In Table C. 6 and Figure C.6, for each range, we list the number of gaps between consecutive numbers in the range. From the table, we see that there are 4 gaps which have the maximum magnitude at $10^{-21}$.

Table 3.1: The smallest difference of $(n, k)$

| $\mathbf{n}$ | $\mathbf{k}$ | $\mathbf{r}(\mathbf{n}, \mathbf{k})$ | Sum of Square Roots |
| :---: | :---: | :---: | :---: |
| 100000 | 2 | $6.58 \times 10^{-18}$ | $(\sqrt{47035}+\sqrt{82802})-(\sqrt{43728}+\sqrt{87330})$ |
| 100 | 2 | $1.53 \times 10^{-07}$ | $(\sqrt{33}+\sqrt{74})-(\sqrt{28}+\sqrt{82})$ |
| 5000 | 3 | $2.84 \times 10^{-20}$ | $(\sqrt{29}+\sqrt{1097}+\sqrt{3153})-(\sqrt{226}+\sqrt{987}+\sqrt{2324})$ |
| 100 | 3 | $8.45 \times 10^{-10}$ | $(\sqrt{31}+\sqrt{48}+\sqrt{98})-(\sqrt{42}+\sqrt{42}+\sqrt{89})$ |
| 1000 | 4 | $9.15 \times 10^{-20}$ | $(\sqrt{154}+\sqrt{381}+\sqrt{770}+\sqrt{774})$ <br> $-(\sqrt{128}+\sqrt{394}+\sqrt{637}+\sqrt{967})$ |
| 100 | 4 | $5.04 \times 10^{-14}$ | $(\sqrt{45}+\sqrt{63}+\sqrt{91}+\sqrt{96})$ <br> $(\sqrt{44}+\sqrt{65}+\sqrt{93}+\sqrt{93})$ |
| 300 | 5 | $1.45 \times 10^{-19}$ | $(\sqrt{101}+\sqrt{131}+\sqrt{185}+\sqrt{211}+\sqrt{212})$ <br> $(\sqrt{61}+\sqrt{128}+\sqrt{154}+\sqrt{264}+\sqrt{269})$ |
| 100 | 5 | $5.66 \times 10^{-15}$ | $(\sqrt{36}+\sqrt{40}+\sqrt{83}+\sqrt{86}+\sqrt{94})$ <br> $-(\sqrt{52}+\sqrt{62}+\sqrt{66}+\sqrt{69}+\sqrt{79})$ |
| 150 | 6 | $3.97 \times 10^{-19}$ | $(\sqrt{34}+\sqrt{36}+\sqrt{57}+\sqrt{76}+\sqrt{92}+\sqrt{149})$ <br> $-(\sqrt{11}+\sqrt{35}+\sqrt{52}+\sqrt{95}+\sqrt{139}+\sqrt{142})$ |
| 100 | 6 | $2.89 \times 10^{-17}$ | $(\sqrt{21}+\sqrt{54}+\sqrt{62}+\sqrt{67}+\sqrt{92}+\sqrt{99})$ <br> $-(\sqrt{15}+\sqrt{59}+\sqrt{76}+\sqrt{76}+\sqrt{82}+\sqrt{90})$ |
| 100 | 7 | $1.88 \times 10^{-19}$ | $\sqrt{7}+\sqrt{14}+\sqrt{39}+\sqrt{70}+\sqrt{72}+\sqrt{76}+\sqrt{85}$ <br> $\sqrt{13}+\sqrt{16}+\sqrt{46}+\sqrt{55}+\sqrt{67}+\sqrt{73}+\sqrt{79}$ |
| 100 | 8 | $2.77 \times 10^{-21}$ | $(\sqrt{16}+\sqrt{43}+\sqrt{43}+\sqrt{46}+\sqrt{60}+\sqrt{85}+\sqrt{89}+\sqrt{95})$ <br> $-(\sqrt{7}+\sqrt{41}+\sqrt{42}+\sqrt{51}+\sqrt{76}+\sqrt{83}+\sqrt{94}+\sqrt{97})$ |

## Chapter 4

## Moderately Hard Functions

### 4.1 Motivation

Functions are mappings from strings to strings. One function can be computed by different algorithms. A function is considered hard if there is no known efficient algorithm to compute it. Easy functions are suitable for completing tasks efficiently while hard ones deter abusers. Cryptographic schemes are built upon these hardness to ensure security. We want, for instance, that finding the inverses of one-way functions is infeasible on any modern computer.

There are situations to apply neither too hard nor too easy functions. Moderately hard functions are suitable and are useful for access control. If it is too easy for a user to send any amount of email to many users, spams will be a problem. A resource is usually shared by different users. To regulate its usage, a user is required to make some extra efforts. That is, the machine needs to spend more time and/or space.

The idea is first introduced by Cynthia Dwork and Moni Naor [DN92]. They call this kind of function a pricing function, as a user needs to pay a fee, in terms of computing resources, in order to use the service. This is a means to discourage abuse of resource. In general, a moderately hard function can be used to implement an access control scheme.

In theoretical computer science and cryptography, a function is generally considered easy if the complexity of its algorithm is in $\mathbf{P}$. Not all polynomial-time algorithms are, however, fast in reality. Users may feel prominent difference in running
algorithms with complexity in $O\left(n^{2}\right)$ and in $O\left(n^{3}\right)$, though both are in $\mathbf{P}$. Moderately hard functions are not well studied but are indeed useful in some situations.

This chapter is organized as follows: Sections 4.2 and 4.3 are the introduction to CPU-bounded moderately hard functions and memory-bounded counterparts; the fourth and the fifth sections contain applications of these ones. The last section gives a formal definition.

### 4.2 CPU-bounded functions

Moderately hard functions can be implemented in two ways: CPU-bounded and memory-bounded. The former emphasizes on time while the later focuses on space. The goal of moderately hard functions is to impose extra costs on computation. It can be accomplished by both means but CPU-bounded ones have their limitation.

When one computes a CPU-bounded function, the majority of work is done by the central processor alone. The speed of CPU decides how fast we can compute. Moderately hard functions aim to slow down a computation, not indefinitely but long enough to feel the delay. As CPU chip technology advances, the slowness of moderately hard CPU-bounded functions gets insignificant.

The CPU-bound may still be an effective means if a new generation CPU makes little progress in processing non-parallelized tasks. The CPU clock rate is an index of processor performance. In year 2000, Vikas Agarwal et al. predicted that the annual clock rate improvement would be $12 \backsim 17 \%$, compared to $50 \backsim 60 \%$ growth in the past AHKB00. Indeed, the CPU design trend has focused on multi-core architectures BDKKMPR05, SC10].

To design moderately hard compute-bound functions against multi-core or manycore CPUs, it is important to make them non-amortized. The final result should be derived from a series of computations. Each intermediate result should be based on
previous ones and none of them can be cached or be omitted.

### 4.3 Memory-bounded functions

Memory-bounded functions impose extra costs for computation in terms of space. Execution of software programs needs space to store intermediate data and/or instructions. A program is composed of data and instructions. They are originally stored on disk. When the program is loaded, they are copied to main memory. As the processor executes the program, related instructions and data will be read/write from/to main memory.

Main memory is separated from CPU chip in hardware design. It takes time to transfer data and instructions between them. The CPU accesses data from registers, located in the CPU chip, almost 100 times faster than from main memory [BO03]. The latency becomes a bottleneck as CPU technology advances and memory unit cost drops. To deal with this issue, system designers made another kind of memory, cache, to store temporary data to be possibly used in the near future. While the main memory is made of dynamic random access memory(DRAM), cache is implemented with static random access memory(SRAM) and runs faster.

Cache acts as a buffer to shorten the memory data access latency. There are two types of caches, L1 and L2. L1 is smaller in size and runs as fast as registers. L2 is 5 to 10 times slower but still runs 5 to 10 times faster than accessing main memory [BO03]. Figure 4.1] shows the hierarchy of memory. The higher the rank, the faster the access time and hence costlier.

Unlike CPU performance advanced fast in the past three decades, the improvements in memory technology is not prominent. The ratio of CPU clock cycle and memory data access latency was 0.3 in 1980 and 220 in 2005, and the gap is still growing [SC10]. To solve this problem, the cache size in current computer archi-
tecture designs has ever increased. Cache misses are expensive, causing delays of hundreds of CPU clock cycles Manferdelli07]. Such bottleneck in performance is called the Memory Wall.

The Memory Wall affects the development of CPU design. From 1990 to 2000, microprocessors have been improving in overall performance at a rate of approximately $50 \backsim 60 \%$ per year AHKB00]. Performance can be evaluated in terms of CPU clock speed, measured in megahertz ( MHz ) or gigahertz ( GHz ). Such rate has decreased greatly in recent years. Instead, the main stream of processor design focuses on multicore CPUs. The change is partly due to the Memory Wall problem [BDKKMPR05].

Memory-bounded functions are designed according to the Memory Wall problem. The major speedup of computer performance, in terms of running a job which cannot be parallelized, is due to a faster CPU rather than memory. When a function designed to be data-access-driven, it will not benefit as much using faster CPU.

The growing divergence between memory data access latency and CPU speed has important applications for moderately hard functions.

Figure 4.1: A memory hierarchy [BO03]

### 4.4 Key derivation functions

A password is an important component of a secure computer system. It is an array of 8 or more characters including letters and decimal digits. It should be easily memorized. To gain access to a computer account, a password is usually required. We can also use a password to encrypt electronic files. In that case, a password does not act directly as an encryption key for a symmetric encryption algorithm such as AES. Instead the encryption key, which is much longer than a password, is generated from the password by a key derivation function. This procedure is particularly important to protect files on laptops, as lost laptops are posed as serious security risks nowadays. Passwords are usually the weakest link in a cryptographic system, since average users of computer systems tend to select passwords which are vulnerable to dictionary attacks.

If laptops are lost to malicious users, they can obtain encrypted file easily. Attackers can then launch off-line exhaustive search attacks on passwords. To slow down the attacks, we need to make sure that the key derivation function takes a while to output a secret key from a password. Key derivation functions are also used to store passwords in a central server. In a system break-in, attackers can obtain the values outputted by a key derivation function from passwords. It is hoped that since key derivation functions are slow, exhaustive searches for passwords would be very expensive.

A common practice of designing key derivation functions is to apply the popular hash functions like MD5 or SHA1 on passwords recursively for several thousand times. As processors speed up, passwords become weaker at the same rate. Once again we see that using space efficient hash functions like MD5 or SHA1 defeats the purpose of achieving security against attackers with improving computer systems.

Algorithm 3 resolves this issue. If we use $M$ as a key derivation function, then we simply let $M(P)$ be the secret key, where $P$ is the password. To save the password on
a server for identity verifications, we store $M(P)$. We choose $l$ such that the function will run for three seconds on middle range computers. By doing that, we can be sure that low-end systems will not suffer a lot in computing $M(P)$, while high-end systems will not gain much in computing $M(P)$. Exhaustive searching for $P$ given $M(P)$ will be infeasible even for high-end machines.

### 4.5 Fighting spams

A large percentage of emails we receive are spams. This, ironically, is due to the low cost and efficiency associated with the email system, the properties that first made it so popular. To alleviate this problem, Dwork and Naor in 1992 proposed to charge senders postage of computation efforts DN92. The idea has been implemented in the HASHCASH proof-of-work system. Suppose that a sender wants to send us a message $m$ that includes her address, our address, the date and the content, etc. We will require her to attach a string $k$ in the email so that the hash value of $m$ and $k$ putting together, i.e. $h(m, k)$, starts with certain a number of zeros. The sender will have to exhaustively search for the string $k$, if the hash function can be modeled as a random oracle. The verification part is simple and fast.

If we use the popular hash functions like MD5 or SHA1, which are designed to be space and time efficient, attackers who possess high-end systems with faster processors will have not much difficulty in finding $k$, if we do not want legitimate senders with only low-end systems to suffer tremendously. On the other hand, if the functions used in finding proof-of-work are space inefficient, not only do we slow the high-end machines that are spreading spam, but we also treat low-end machines more fairly, which often need to send many legitimate emails. In light of this, researchers ABMW03, DGN03] started to investigate space inefficient hash functions that will access the main memory frequently and randomly during the computation.

Abadi et al. ABMW03 proposed functions based on inverting of prescribed functions. To prevent the time-space tradeoff attack, Dwork et al. DGN03] proposed to use functions that read random positions in a big table (for the current configuration, a table of size 16 Mbytes is good enough). The table has to look random. One way to achieve that is to fix a truly random string, i.e. a bit string with high Kolmogorov complexity. But a long random string will greatly increase the size of email client programs. After all, adding 16 Mbytes to email clients is not very appealing. Can we generate such a table using a short program that runs in large space? Dwork et al. DNW05] designed a graph theoretic method to generate large tables from short inputs, but the procedure is quite involved.

The Dwork et al.'s space inefficient hash function $M$ is built on hash functions $H_{0}, H_{1}, H_{2}$ and $H_{3}$, and a large array $T . T$ is a big table and cannot be entirely placed into cache. Algorithm 3 is copied from DNW05 for completeness.

```
Algorithm 4.1: The space inefficient hash function \(M\) [DNW05]
    Input: \(m, l\)
    \(A=H_{0}(m)\);
    while \(l \neq 0\) do
        \(c=H_{1}(A)\);
        \(A=H_{2}(A, T[c])\);
        \(l=l-1 ;\)
    end
    return \(H_{3}(A)\)
```

The time of accessing memory should be the dominating part of the computation, so the hash functions $H_{1}$ and $H_{2}$ in the above program need to be time and space efficient. The size of $A$ need to be determined carefully. See [DGN03] for details. As for $H_{0}$ and $H_{3}$, it is a good idea to use MD5 or SHA1. Even though they have weakness in collision resistance, it does not affect this application.

For fighting spam, an email sender is required to attach a bit string $k$ to her message $m$ such that a certain number of bits at the beginning of $M(m, k)$ are all
zeros. We select a number $l$ so that the time to find a $k$ takes about 10 seconds in a middle range computer. We should not require every sender to attach a proof-of-work. Doing this would impose too much overhead on email systems. We note that most of legitimate emails we receive are from addresses that have sent us legitimate emails before. Therefore we need to maintain a list of trusted addresses and domains, and require only the sender from an address not in the list to attach a proof-of-work. The procedure needs to be handled automatically by the system. This greatly reduces the workload of some centralized email servers like Gmail. If combined with other tools such as filters, we believe that it will significantly reduce the amount of spams.

### 4.6 Formal definition of memory-bounded functions

Since we want the output of a memory-bounded function to look random, it is natural to first examine pseudo-random generators, which are one of the most important cryptographic primitives. There is vast literature on the topic. But most of pseudorandom number generators are not good for the purpose, because given short random inputs, they can be computed in a space efficient manner. Furthermore, most of pseudo-random generators are based on hash chains and they suffer from the timespace tradeoff attacks. Let $h$ be a cryptographic hash function like MD5 or SHA1. Let $r_{0}$ be a random string. We can build a hash chain of length $e$ by defining

$$
r_{i}=h\left(r_{i-1}\right), 0 \leq i \leq e-1 .
$$

How fast can we compute $r_{i}$ for a random $i$ ? If we have about one unit of space (assume that each unit can hold one value in the chain), then we have to apply the hash function $i$ times to compute $r_{i}$. On average, it takes $O(e)$ hash applications to compute a random element in the hash chain. On the other hand, given $s$ memory
units, we can pre-compute a table

$$
r_{0}, r_{\lfloor e / s\rfloor}, r_{\lfloor 2 e / s\rfloor}, \cdots, r_{\lfloor(s-1) e / s\rfloor}
$$

which may be regarded as hints for computing the hash chain. Then on average it takes only $O(e / s)$ hash applications to compute an element in the chain. More space allows a more efficient algorithm to compute an element in the chain. This is an example of time-space trade-off.

Time-space trade-off attack is not acceptable to memory-bounded functions. Instead, if space is below a certain point (close to the size of the output), no polynomial time algorithm should exist to compute any part of the output. This motivates the following definition of memory-bounded function.

Definition 4.6.1. We call a function $\mathbf{F}:\{0,1\}^{r} \rightarrow\left(\{0,1\}^{s}\right)^{e}$ memory-bounded, if

- the function can be computed in time polynomial in $r$;
- there exists a subset $S$ of $\{0,1\}^{r}$ with cardinality greater than $2^{r}-2^{r / 2}$, such that for any function $h:\{0,1\}^{r} \rightarrow\left(\{0,1\}^{s}\right)^{e / 2}$, for any polynomial time algorithm $A$ running in space of $s e / 2+\log e$ bits and for all $a \in S$, we have

$$
|\{i \mid 1 \leq i \leq e, A(h(a), i)=\mathbf{F}(a)[i]\}| \leq \frac{e}{2}+\frac{e}{s} .
$$

Remark: Inevitably there are inputs $a$ of $\mathbf{F}$ that $\mathbf{F}(a)[i]$ can be computed in space efficient manner for any $i$, but the number of them should be small. In the above definition, the number is less than $2^{r / 2}$.

Remark: Elements in output array usually belong to the set $\{0,1,2, \cdots, q-$ $2, q-1\}$ where $2^{s-1} \leq q \leq 2^{s}$. So a $s e / 2$-bit data can potentially hold $e / 2+e / s$ elements.

Remark: There is no requirement for the computational complexity of the function $h$. One should consider $h(a)$ as hints, which may be pre-computed to facilitate a space efficient algorithm to compute $\mathbf{F}(a)[i]$.

Remark: If $h(a)$ consists of part of the output array $\mathbf{F}(a)$, then we can read $e / 2+e / h$ elements in the array. But by definition, there is no algorithm that can compute one more element in the limited space of $s e / 2$ bits.

To summarize the definition, even though the output is generated from a short input, it behaves like a random string to a machine with only limited space.

Theorem 4.6.2. Assume that $H_{0}, H_{1}, H_{2}, H_{3}$ are random oracles in the algorithm defining $M$. If we implement $T$ by using the output generated by a memory-bounded function $\mathbf{F}$ with a random input of $s$ bits and with $l>r$, the algorithm $M$ will have $l / 3$ many cache misses with probability greater than $1-0.95^{l}$.

Intuitively during the computation of $M$, it is unlikely that the value of $A$ will repeat. The location of access, $c$, cannot be predicted if the hash function $H_{1}$ can be modeled as a random oracle. If the cache has size se/2 or less, then the probability of cache miss would be at least $1 / 2-1 / s$, since at most $e / 2+e / s$ many elements in $T$ can be computed using only caches.

Proof. If an input $a$ of $\mathbf{F}$ was selected randomly, then with probability $1-\frac{1}{2^{r / 2}}, a \in S$. In any of the $l$ iterations of the loop of $M$, assume that cache content is $C$ at the beginning of the iteration and the computer is running an algorithm $A$ to compute $\mathbf{F}(a)[c]$. If there is no cache miss, then

$$
c \in\{i \mid 1 \leq i \leq e, A(C, i)=\mathbf{F}(a)[i]\} .
$$

Since $c$ is computed from a random oracle $H_{1}$, according to definition of memorybounded functions, no cache miss happens with probability less than or equal to
$1 / 2+1 / s$. For $l$ iterations, the algorithm has $l / 3$ or less cache misses with a probability of

$$
\sum_{1 \leq i \leq l / 3}\binom{l}{i}(1 / 2+1 / s)^{l-i}(1 / 2-1 / s)^{i}<\frac{\binom{l}{\lceil l / 3\rceil}}{2^{l}}<0.944^{l} .
$$

The algorithm has $l / 3$ or more cache miss with probability at least $\left(1-0.707^{r}\right)(1-$ $\left.0.944^{l}\right)>1-0.95^{l}$.

## Chapter 5

## Number Theoretic Constructions

### 5.1 Motivation

Number theoretic functions form the backbone of public-key cryptosystems. Computationally cryptography related number theoretic functions are mostly modular exponentiations, or their variations, such as elliptic curve point multiplications. A large amount of work has been done to improve the efficiency of modular exponentiations, but they are notoriously slow, comparing with symmetric encryption/decryption and popular hash functions. On the other hand, usually modular exponentiations can be evaluated in a small amount of space, hence they are not memory-bounded. For instance $a^{b}(\bmod n)(a, b, n$ are positive integers and $a, b<n)$ can be computed in $O(\log n)$ space, and the output size is not larger than the input size.

### 5.2 Construction

We consider the exponentiation $(1+x)^{n}\left(\bmod p, x^{e}-a\right)$. If

$$
\begin{equation*}
(1+x)^{n} \quad\left(\bmod p, x^{e}-a\right)=c_{0}+c_{1} x+c_{2} x^{2}+\cdots+c_{e-1} x^{e-1} \tag{5.2.0.1}
\end{equation*}
$$

we formally define $F_{p, e, a}$ to be

$$
F_{p, e, a}(n)=\left(c_{0}, c_{1}, \cdots, c_{e-1}\right) \in \mathbf{F}_{p}^{e}
$$

First observe that an input has size $O(\log p)$ bits if we require that $n<p$ and that $e$ is about $(\log p)^{O(1)}$. The function can be computed in polynomial time using $O(e \log p)$ bit space. However there is no known efficient algorithm to compute any part of coefficient using less than $e \log p$ space. The condition that $x^{e}-a$ is irreducible is crucial here, for otherwise the ring $\mathbf{F}_{p}[x] /\left(x^{e}-a\right)$ can be split, and the computation can be done in smaller space.

Notice that the $i$-th coefficient can indeed be computed in smaller space by evaluating the expression

$$
c_{i}=\sum_{e j+i \leq n}\binom{n}{e j+i} a^{j} \quad(\bmod p)
$$

term by term. But the method will take exponential time, because not only the number of terms is exponential in $\log n$, but also each term involves factorial-like functions, which are hard to compute individually.

Conjecture 5.2.1. The function $F_{p, a, e}$ is memory-bounded.

One might ask whether for a small $\tau$, there exist hints $h_{1}, h_{2}, \cdots, h_{\tau} \in \mathbf{F}_{p}$ depending on $n$, and an algorithm that, given $i$, computes the $c_{i}$ in 5.2.0.1) from $i$ and $h_{1}, h_{2}, \cdots, h_{\tau}$. The following lemma shows that this is impossible when there is no restriction on $n$.

Theorem 5.2.2. Denote the order of $1+x$ in the field $\mathbf{F}_{p}[x] /\left(x^{e}-a\right)$ by ord $(1+x)$. Let $\tau$ be an integer less than $\log _{p} \operatorname{ord}(1+x)$. For any functions $f_{0}, f_{1}, \cdots, f_{e-1}$, there do not exist functions $h_{1}, h_{2}, \cdots, h_{\tau}$ in $\mathbf{Z}_{\leq p^{e}}^{+} \rightarrow \mathbf{F}_{p}$ such that

$$
\begin{gathered}
(1+x)^{n} \quad\left(\bmod p, x^{e}-a\right) \\
=\sum_{0 \leq i \leq e-1} f_{i}\left(h_{1}(n), h_{2}(n), \cdots, h_{\tau}(n)\right) x^{i}
\end{gathered}
$$

for all $1 \leq n \leq p^{e}$.

Proof. The theorem can be proved by a counting argument. Fix any function $f_{0}, f_{1}, \cdots, f_{e-1}$ and $h_{1}, h_{2}, \cdots, h_{\tau}$,

$$
\begin{aligned}
& \left|\left\{\sum_{0 \leq i \leq e-1} f_{i}\left(h_{1}(n), h_{2}(n), \cdots, h_{\tau}(n)\right) x^{i}\right\}\right| \\
\leq & \mid\left\{\left(\hat{h}_{1}, \hat{h}_{2}, \cdots, \hat{h}_{\tau}\right) \mid \hat{h}_{i} \in \mathbf{F}_{p} \text { for } 1 \leq i \leq \tau\right\} \mid \\
= & p^{\tau}<\operatorname{ord}(1+x),
\end{aligned}
$$

but

$$
\left|\left\{(1+x)^{n} \quad\left(\bmod p, x^{e}-a\right) \mid 1 \leq n \leq p^{e}\right\}\right|=\operatorname{ord}(1+x)
$$

thus

$$
\begin{gathered}
(1+x)^{n} \quad\left(\bmod p, x^{e}-a\right)= \\
\sum_{0 \leq i \leq e-1} f_{i}\left(h_{1}(n), h_{2}(n), \cdots, h_{\tau}(n)\right) x^{i}
\end{gathered}
$$

can not hold for all $1 \leq n \leq p^{e}$.

Remark: Usually the order of $1+x$ is close to $p^{e}$, hence the size of hints has to be very large in order for an algorithm to compute the coefficient in a space efficient manner. The theorem does not prove that $F$ is memory-bounded, because we require that $n \leq p$ in $F$. But it does serve as a support evidence to the conjecture that $F$ is memory-bounded.

### 5.3 Memory-efficient exponentiating method

In Section 5.2, modular arithmetics refers to calculating in/between equivalent classes according to the modulus. Let $a, q, m, b \in \mathbb{Z}, a=q m+b$, where $q$ is quotient and $0 \leq b<m$ is residue. The modulus $m$ partitions $\mathbb{Z}$ into $m$ equivalent classes. $a \equiv b$ $(\bmod m)$ means that $a$ and $b$ are equivalent.

Modular exponentiation corresponds to repeated multiplication of the same base for exponent number of times. The product is an integer between 0 and $m$ so does any intermediate result. Modular exponentiation has lots of applications in the field of cryptography. Take the famous RSA scheme as example, the ciphertext $c \equiv m^{e}$ $(\bmod n)$, where $m$ is the plaintext and $n, e$ together is the public key. Both encryption and decryption rely on modular exponentiation. The speed of exponentiation determines practicability of these schemes.

The naive way of deriving $b^{e}(\bmod m)$ is first calculate $b^{e}$ and then modulo it by $m$. Say we are interested in finding $7^{50}(\bmod 19)$. The first step results in

1798465042647412146620280340569649349251249,
which needs 43 decimal digits of space to proceed next step while 7 and 50 need at most 2. The space requirement of this method is $O(e \log b)$ and time is $O(e)$.

Observing the fact below, exponentiation can be divided into multiple square steps. And we can apply modulo on each intermediate product to reduce the space requirement.

## Observation 1.

$$
\begin{aligned}
& b^{2} \quad(\bmod m) \\
& \equiv\left(\begin{array}{ll}
b & (\bmod m))(b \quad(\bmod m)) \quad(\bmod m) \\
\equiv(b \quad(\bmod m))^{2} \quad(\bmod m)
\end{array}\right.
\end{aligned}
$$

Integers are represented in binary format in computers. Multiplication by 2 can be done efficiently by just shifting $n$ bit to the left, where $n$ is the number of bits required to represent that integer. Squaring requires only $n$ bit-operations rather
than multiplying. Shifting $n$-bits can be done faster than multiply an integer by 2. According to this, the following algorithm dramatically reduces time and space requirement. Compared to the intuitive method, it does $O(\log e)$ multiplications and needs $O(\log m)$ in space.

```
Algorithm 5.1: Exponentiating by squaring [Schneier96]
    Input: base \(b\), exponent \(e\), modulus \(m\)
    Output: result
    result \(:=1\);
    while \(e>0\) do
        if \((e \& 1)==1\) then
            result \(:=(\) result \(* b)(\bmod m) ;\)
        end
        \(e:=e \gg 1\);
        \(b:=(b * b)(\bmod m) ;\)
    end
    return result
```

This technique applies on the situation $(1+x)^{n}\left(\bmod p, x^{e}-a\right)$, where $p$ is a prime number and $n, e, a$ are in $\mathbb{Z}$. The time requirement is $O(\log n)$ and space is $O(e \log p)$. For example, $(1+x)^{50}\left(\bmod 79, x^{26}-3\right)$ is congruent to

$$
\begin{array}{r}
57 x^{25}+73 x^{24}+63 x^{23}+57 x^{22}+77 x^{21}+11 x^{20}+20 x^{19}+32 x^{18}+28 x^{17} \\
+61 x^{16}+x^{15}+46 x^{14}+68 x^{13}+17 x^{12}+72 x^{11}+78 x^{10}+77 x^{9}+7 x^{8} \\
+9 x^{7}+32 x^{6}+62 x^{5}+71 x^{4}+9 x^{3}+9 x^{2}+26 x+53
\end{array}
$$

It is hard to derive the coefficient of certain term without using $O(e \log p)$ space. For each iteration of while loop, the algorithm squares base and then does modulo. These intermediate results take up space.

### 5.4 Closed form observation

One criterion of choosing a memory bounded function is to show that there is no shortcut way to derive any partial results. In the case of $(1+x)^{n}\left(\bmod p, x^{e}-a\right)$, we are looking for evidence of deriving some binomial coefficients using small memory space. $(1+x)^{n}\left(\bmod p, x^{e}-a\right)$ will be a good candidate of memory bound if we cannot find such certificate.

The binomial formula $(x+y)^{n}=\sum_{k=0}^{n}\binom{n}{k} x^{n-k} y^{k}$ relates to our goal. We are interested in computing sums of binomial coefficients in small space, or calculate it directly, where $k$ is not consecutive integers. More generally, we consider the case of Definition 5.4.3.

Definition 5.4.1. $\forall n, k \in \mathbb{Z},\binom{n}{k} \stackrel{\text { def }}{=} \frac{n(n-1)(n-2) \cdots(n-k+1)}{k!}$.
Definition 5.4.2. $\forall n, k \in \mathbb{Z},\binom{n}{k} \stackrel{\text { def }}{=} 0$ if $k<0, k>n$, or $n \leq 0$.

## Definition 5.4.3.

$$
f_{i}(n, l) \stackrel{\text { def }}{=} \sum_{0 \leq k \leq n}\binom{n}{l k-i}, \text { where } i, l \in \mathbb{N} \text { and } 0 \leq i \leq l
$$

One way to compute $f_{i}(n, l)$ in small space is to express it in closed form. For a fixed $n$ and $i, f_{i}(n, l)$ becomes a series as $l$ varies. A closed form exhibits a series as a sum of a fixed (independent of $n$ ) number of hypergeometric terms.

A geometric series $\sum_{k \geq 0} t_{k}$ is one in which the ratio of every two consecutive terms is constant, i.e., $\frac{t_{k+1}}{t_{k}}$ is a constant function of the summation index $k$. A hypergeometric series $\sum_{k \geq 0} t_{k}$ is one in which $t_{0}=1$ and the ratio of two consecutive terms is a rational function of the summation index $k$, i.e., in which

$$
\frac{t_{k+1}}{t_{k}}=\frac{P(k)}{Q(k)}
$$

where $P$ and $Q$ are polynomials in $k$. Examples of such hypergeometric terms are $t_{k}=x^{2 k}$ or $t_{k}=\frac{(3 k-8)!}{(k+1)!}$.

Definition 5.4.4 (Hypergeometric closed form [PWZ96]). A function $f(n)$ is said to be of closed form if it is equal to a linear combination of a fixed number, $r$, say, of hypergeometric terms. The number $r$ must be an absolute constant, i.e., it must be independent of all variables and parameters of the problem.

Petkovsek et al. PWZ96] developed computer programs for simplifying sums that involve binomial coefficients. Their algorithm, Hyper, outputs all hypergeometric closed forms of a recursive relation. A recurrence relation is an equation that recursively defines a sequence: each term of the sequence is defined as a function of the preceding terms.

We are going to find a recursive relation for $f_{i}(n, l)$ and start with a special case.

## Definition 5.4.5.

$$
f_{i}(n) \stackrel{\text { def }}{=} \sum_{0 \leq k \leq n}\binom{n}{3 k-i} .
$$

## Observation 2.

$$
\begin{aligned}
& f_{0}(n+1)=f_{0}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k-1}=f_{0}(n)+f_{1}(n) \\
& f_{1}(n+1)=f_{1}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k-2}=f_{1}(n)+f_{2}(n) \\
& f_{2}(n+1)=f_{2}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k}=f_{2}(n)+f_{0}(n)
\end{aligned}
$$

Lemma 5.4.6. $2 f_{i}(n)-3 f_{i}(n+1)+3 f_{i}(n+2)-f_{i}(n+3)=0$ is the recursive relation of $f_{i}(n)$.

Proof. The proof is done by induction on $n$.

1. When $n=1$, we have

$$
\begin{aligned}
& 2 f_{0}(1)-3 f_{0}(2)+3 f_{0}(3)-f_{0}(4)=2-3+6-5=0 . \\
& 2 f_{1}(1)-3 f_{1}(2)+3 f_{1}(3)-f_{1}(4)=0-3+9-6=0 . \\
& 2 f_{2}(1)-3 f_{2}(2)+3 f_{2}(3)-f_{2}(4)=2-6+9-5=0 .
\end{aligned}
$$

2. Assume

$$
\begin{aligned}
& 2 f_{0}(n)-3 f_{0}(n+1)+3 f_{0}(n+2)-f_{0}(n+3)=0 \text { and } \\
& 2 f_{1}(n)-3 f_{1}(n+1)+3 f_{1}(n+2)-f_{1}(n+3)=0 \text { and } \\
& 2 f_{2}(n)-3 f_{2}(n+1)+3 f_{2}(n+2)-f_{2}(n+3)=0 .
\end{aligned}
$$

3. Want to show $2 f_{0}(n+1)-3 f_{0}(n+2)+3 f_{0}(n+3)-f_{0}(n+4)=0$.

$$
\begin{aligned}
& 2 f_{0}(n+1)-3 f_{0}(n+2)+3 f_{0}(n+3)-f_{0}(n+4) \\
= & 2\left(f_{0}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k-1}\right)-3\left(f_{0}(n+1)+\sum_{0 \leq k \leq n+1}\binom{n+1}{3 k-1}\right) \\
& +3\left(f_{0}(n+2)+\sum_{0 \leq k \leq n+2}\binom{n+2}{3 k-1}\right)-\left(f_{0}(n+3)+\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k-1}\right) \\
= & 2 \sum_{0 \leq k \leq n}\binom{n}{3 k-1}-3 \sum_{0 \leq k \leq n+1}\binom{n+1}{3 k-1}+3 \sum_{0 \leq k \leq n+2}\binom{n+2}{3 k-1}-\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k-1} \\
= & 2 f_{1}(n)-3 f_{1}(n+1)+3 f_{1}(n+2)-f_{1}(n+3) \\
= & 2 f_{1}(n+1)-3 f_{1}(n+2)+3 f_{1}(n+3)-f_{1}(n+4) \\
= & 2\left(f_{1}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k-2}\right)-3\left(f_{1}(n+1)+\sum_{0 \leq k \leq n+1}\binom{n+1}{3 k-2}\right) \\
& +3\left(f_{1}(n+2)+\sum_{0 \leq k \leq n+2}\binom{n+2}{3 k-2}\right)-\left(f_{1}(n+3)+\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k-2}\right)
\end{aligned}
$$

$$
\begin{aligned}
= & 2 \sum_{0 \leq k \leq n}\binom{n}{3 k-2}-3 \sum_{0 \leq k \leq n+1}\binom{n+1}{3 k-2}+3 \sum_{0 \leq k \leq n+2}\binom{n+2}{3 k-2}-\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k-2} \\
= & 2 f_{2}(n)-3 f_{2}(n+1)+3 f_{2}(n+2)-f_{2}(n+3) \\
= & 2 f_{2}(n+1)-3 f_{2}(n+2)+3 f_{2}(n+3)-f_{2}(n+4) \\
= & 2\left(f_{2}(n)+\sum_{0 \leq k \leq n}\binom{n}{3 k}\right)-3\left(f_{2}(n+1)+\sum_{0 \leq k \leq n+1}\binom{n+1}{3 k}\right) \\
& +3\left(f_{2}(n+2)+\sum_{0 \leq k \leq n+2}\binom{n+2}{3 k}\right)-\left(f_{2}(n+3)+\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k}\right) \\
= & 2 \sum_{0 \leq k \leq n}\binom{n}{3 k}-3 \sum_{0 \leq k \leq n+1}\binom{n+1}{3 k}+3 \sum_{0 \leq k \leq n+2}\binom{n+2}{3 k}-\sum_{0 \leq k \leq n+3}\binom{n+3}{3 k} \\
= & 2 f_{0}(n)-3 f_{0}(n+1)+3 f_{0}(n+2)-f_{0}(n+3) \\
= & 0
\end{aligned}
$$

Lemma 5.4.6 can be further generalized.

## Lemma 5.4.7.

$$
\begin{aligned}
f_{0}(n+1, l) & =f_{0}(n, l)+f_{1}(n, l) \\
f_{1}(n+1, l) & =f_{1}(n, l)+f_{2}(n, l) \\
f_{2}(n+1, l) & =f_{2}(n, l)+f_{3}(n, l) \\
& \vdots \\
f_{l-1}(n+1, l) & =f_{l-1}(n, l)+f_{0}(n, l)
\end{aligned}
$$

Proof. According to Pascal's rule, the proof is straight forward.

$$
f_{0}(n+1, l)=\sum_{0 \leq k \leq n}\binom{n}{l k}+\sum_{0 \leq k \leq n}\binom{n}{l k-1}=f_{0}(n, l)+f_{1}(n, l) .
$$

$$
\begin{aligned}
f_{1}(n+1, l) & =\sum_{0 \leq k \leq n}\binom{n}{l k-1}+\sum_{0 \leq k \leq n}\binom{n}{l k-2}=f_{1}(n, l)+f_{2}(n, l) \\
f_{2}(n+1, l) & =\sum_{0 \leq k \leq n}\binom{n}{l k-2}+\sum_{0 \leq k \leq n}\binom{n}{l k-3}=f_{2}(n, l)+f_{3}(n, l) . \\
& \vdots \\
f_{l-1}(n+1, l) & =\sum_{0 \leq k \leq n}\binom{n}{l k-l+1}+\sum_{0 \leq k \leq n}\binom{n}{l k}=f_{l-1}(n, l)+f_{0}(n, l) .
\end{aligned}
$$

Definition 5.4.8 (Operator $N) . \forall k \in \mathbb{Z}, f_{i}(n, l) N^{k} \stackrel{\text { def }}{=} f_{i}(n+k, l)$ and $f_{i}(n, l) / N^{k} \stackrel{\text { def }}{=}$ $f_{i}(n-k, l)$.

Lemma 5.4.9. $f_{i}(n, l)\left(1+(1-N)^{l}\right)=0$ is the recursive relation of $f_{i}(n, l)$, where $2 \nmid l$.

Proof. The proof is done by induction on $n$.

1. When $n=0$, we have

$$
f_{i}(0, l)\left(1+(1-N)^{l}\right)=\left(\sum_{0 \leq k \leq n}\binom{0}{l k-i}\right)\left(1+(1-N)^{l}\right)=0, \forall i
$$

2. Assume $f_{i}(n, l)\left(1+(1-N)^{l}\right)=0, \forall i$.
3. $f_{0}(n+1, l)\left(1+(1-N)^{l}\right)=\left(f_{0}(n, l)+f_{1}(n, l)\right)\left(1+(1-N)^{l}\right)=0$. Similarly, it holds for all other $i$.

Lemma 5.4.10. $\frac{n}{N} f_{i}(n, l)\left(1-(1-N)^{l}\right)=0$ is the recursive relation of $f_{i}(n, l)$, where $2 \mid l$.

Proof. The proof is done by induction on $n$.

1. When $n=0$, we have

$$
\frac{0}{N} f_{i}(0, l)\left(1-(1-N)^{l}\right)=0, \forall i
$$

2. Assume $\frac{n}{N} f_{i}(n, l)\left(1-(1-N)^{l}\right)=0, \forall i$.
3. $\frac{n+1}{N} f_{0}(n+1, l)\left(1-(1-N)^{l}\right)=\frac{n+1}{N}\left(f_{0}(n, l)+f_{1}(n, l)\right)\left(1-(1-N)^{l}\right)$
$=0$. Similarly, it holds for all other $i$.

The process of deriving closed form solutions of a function containing binomial coefficients involves two steps [PWZ96]:

- Step 1: Convert a summand function into recurrence.
- Step 2: Find all closed form solutions for the recurrence.

The first step is done by Zeilberger's algorithm, which fast discovers the recurrence for a proper hypergeometric term. The second part is finished by the algorithm Hyper. They have been implemented as Maple and Mathematica programs respectively. Table 5.1 shows the inputs and outputs of Zeilberger's algorithm, program $c t$. In case of $y(n)=\sum\binom{n}{8 k}$ and higher, the program ct returns the following: Error, (in ct) cannot determine if this expression is true or false: FAIL $<0$.

Figure 5.1 shows outputs from the algorithm Hyper by plugging first five recurrences from above table. As $l$ increases, the level of recurrence increases, which means higher space complexity.

When Hyper returns the empty brackets " $\}$ ", it signifies the absence of hypergeometric solutions. If it returns 2, for instance, the answer corresponds to $y(n)=2^{n}$.

Figure 5.1: Outputs from the algorithm Hyper

Table 5.1: Inputs and outputs of Zeilberger's algorithm

| Input | Output |
| :---: | :---: |
| $y(n)=\sum\binom{n}{3 k}$ | $2 y(n)-3 y(n+1)+3 y(n+2)-y(n+3)=0$ |
| $y(n)=\sum\binom{n}{4 k}$ | $4 n y(n)-6 n y(n+1)+4 n y(n+2)-n y(n+3)=0$ |
| $y(n)=\sum\binom{n}{5 k}$ | $2 y(n)-5 y(n+1)+10 y(n+2)$ <br> $-10 y(n+3)+5 y(n+4)-y(n+5)=0$ |
| $y(n)=\sum\binom{n}{6 k}$ | $6 n y(n)-15 n y(n+1)+20 n y(n+2)$ <br> $-15 n y(n+3)+6 n y(n+4)-n y(n+5)=0$ |
| $y(n)=\sum\binom{n}{7 k}$ | $2 y(n)-7 y(n+1)+21 y(n+2)-35 y(n+3)$ <br> $+35 y(n+4)-21 y(n+5)+7 y(n+6)-y(n+7)=0$ |

Hence, for the case of $f_{i}(n, l)$, we conjecture that there is no closed form solution when $2 \mid l$.

### 5.5 Conclusion

Popular hash functions are designed to be collision resistant and to be space efficient. Space efficiency is an undesired property in fighting spam and in deriving secret keys from short passwords. We hardly need to worry about collisions in these applications, since passwords are very short, and collisions do not help to decrease the effort to find proof-of-work. We propose to use the space inefficiency of exponentiations of sparse polynomials to build memory-bounded functions. They can be used to design space inefficient hash functions.

## Chapter 6

## Conclusion and Future Work

The time and space trade-off technique helps a lot in finding lower bound of the sum-of-square-roots problem, a famous open problem in computational geometry. In this dissertation, an upper bound is presented along with a space-efficient algorithm to find $r(n, k)$ exactly in $n^{k+o(k)}$ time and in $n^{\lceil k / 2\rceil+o(k)}$ space. As an example, $r(100,7)$ is calculated in a few hours on one PC and $r(100,8)$ in about one month. Numerical data seems to suggest that our upper bound is better than the root separation bounds. Further investigation, both experimental and theoretical, is needed.

Moderately hard functions have been proposed to combat junk emails. One way to implement is by utilizing the memory bound. Memory-bounded functions incorporate random walks in memory space. They use time and space trade-off technique with emphasis on large memory usage and hence properly slow down CPU throughput. High-end computers do not enjoy much acceleration than low-ends. These functions are essentially hash functions with a special constraint.

Popular hash functions are designed to be collision resistant and space efficient. Space efficiency is an undesired property in fighting spam and in deriving secret keys from short passwords. We hardly need to worry about collisions in these applications, since passwords are very short, and collisions do not help to decrease the effort to find proof-of-work. Moderately hard memory-bounded functions can be considered as memory-inefficient hash functions.

A formal definition of memory-bounded functions is given in Chapter4. This is the first to the best of our knowledge. Hard number theoretic functions form foundations
of modern cryptography. Based on the definition, we aim to construct tables in a number theoretical way.

Chapter 5 demonstrates how to build such tables. Compelling a computer to randomly walk in memory space relies on a table with uniformly distributed data. Such tables should be constructed effortlessly so that they can be shared even though they take lot of memory space. This is an important requirement for practical concerns.

The future goal is to prove a function memory-bounded. We have reasons to conjecture that the constructed table will make a function memory-bounded. It would be nice to find out a proof.

## Appendices

## Appendix A

## Proof of Linear Independence

Definition A.0.1. Let $a_{1}, a_{2}, \cdots, a_{h} \in \mathbb{Z}$ be not all zeros. Define a set of linear expressions

$$
L\left(x_{1}, x_{2}, \cdots, x_{h}\right) \stackrel{\text { def }}{=}\left\{a_{1} x_{1} \pm a_{2} x_{2} \pm \cdots \pm a_{h} x_{h}\right\}
$$

which contains all combinations of sign of each term.

There are $2^{h-1}$ elements in $L\left(x_{1}, x_{2}, \cdots, x_{h}\right)$.

Definition A.0.2. Let $T \in \mathbb{Z} \backslash\{0\}$ be a variable.

$$
F_{L, x_{1}, x_{2}, x_{3}, \cdots, x_{h}}(T) \stackrel{\text { def }}{=} \prod_{e \in L}(T-e)=\prod\left(T-\left(a_{1} x_{1} \pm a_{2} x_{2} \pm a_{3} x_{3} \pm \cdots \pm a_{h} x_{h}\right)\right)
$$

Note that changing the sign of any of $x_{2}, x_{3}, \cdots, x_{h}$ only re-permutes the set $L\left(x_{1}, x_{2}, \cdots, x_{h}\right)$. So, $F_{L, x_{1}, x_{2}, x_{3}, \cdots, x_{h}}(T)=F_{L, x_{1}, \pm x_{2}, \pm x_{3}, \cdots, \pm x_{h}}(T)=\prod\left(T-a_{1} x_{1} \pm\right.$ $a_{2} x_{2} \pm a_{3} x_{3} \pm \cdots \pm a_{h} x_{h}$ ). This implies that the power of $x_{2}, x_{3}, \cdots, x_{h}$ are even in the expanded form of $F_{L, x_{1}, x_{2}, \cdots, x_{h}}(T)$.

The power of $x_{1}$ can be even or odd. We treat $F_{L, x_{1}, \cdots, x_{h}}(T)$ as a polynomial of $x_{1}, x_{2}, \cdots, x_{h}$ and group its expanded form by parity of $x_{1}$.

$$
F_{L, x_{1}, \cdots, x_{h}}(T)=x_{1} P\left(x_{1}^{2}, x_{2}, x_{3}, \cdots, x_{h}, T\right)+Q\left(x_{1}^{2}, x_{2}, x_{3}, \cdots, x_{h}, T\right)
$$

where $P$ contains monomials with power of $x_{1}$ is odd and $Q$ does that with even
power. Since the power of $x_{2}, x_{3}, \cdots, x_{h}$ are even in the expanded form, we can write

$$
F_{L, x_{1}, \cdots, x_{h}}(T)=x_{1} P^{\prime}\left(x_{1}^{2}, x_{2}^{2}, x_{3}^{2}, \cdots, x_{h}^{2}, T\right)+Q^{\prime}\left(x_{1}^{2}, x_{2}^{2}, x_{3}^{2}, \cdots, x_{h}^{2}, T\right)
$$

Note that $P^{\prime}$ and $Q^{\prime}$ generate integers if $x_{1}^{2}, x_{2}^{2}, x_{3}^{2}, \cdots, x_{h}^{2}$, and $T$ are all integers.

Proposition A.0.3. Let $n_{1}, n_{2}, \cdots, n_{N}$ be square-free numbers and $a_{1}, a_{2}, \cdots, a_{N} \in$ $\mathbb{Z}$ be not all zeros.

$$
\sum_{1 \leq i \leq N} a_{i} \sqrt{n_{i}} \notin \mathbb{Z} \backslash\{0\}
$$

Proof. Boreico08] Prove by induction on $N$. When $N=1$, it is clear. Assume on the contradiction that $a_{1} \sqrt{n_{1}}+a_{2} \sqrt{n_{2}}+\cdots+a_{h} \sqrt{n_{h}}=M \in \mathbb{Z} \backslash\{0\}$. By definition, $L\left(\sqrt{n_{1}}, \sqrt{n_{2}}, \cdots, \sqrt{n_{h}}\right)=\left\{a_{1} \sqrt{n_{1}} \pm \cdots \pm a_{h} \sqrt{n_{h}}\right\}$. We have $F_{L, \sqrt{n_{1}}, \sqrt{n_{2}}, \cdots, \sqrt{n_{h}}}(M)=$ $\prod_{e \in L}(M-e)=0$. We also have $F_{L, \sqrt{n_{1}}, \sqrt{n_{2}}, \cdots, \sqrt{n_{h}}}(M)=\sqrt{n_{1}} P^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)+$ $Q^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)=0$. So,

$$
P^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)=Q^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)=0
$$

Hence, $-\sqrt{n_{1}} P^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)+Q^{\prime}\left(n_{1}, n_{2}, \cdots, n_{h}, M\right)=F_{L,-\sqrt{n_{1}}, \sqrt{n_{2}}, \cdots, \sqrt{n_{h}}}(M)=$ $\Pi\left(M+a_{1} \sqrt{n_{1}} \pm a_{2} \sqrt{n_{2}} \pm a_{3} \sqrt{n_{3}} \pm \cdots \pm a_{h} \sqrt{n_{h}}\right)=0$.

Therefore, $M=-a_{1} \sqrt{n_{1}} \pm a_{2} \sqrt{n_{2}} \pm \cdots \pm a_{h} \sqrt{n_{h}}$ for some combination of sign. But we have assumed that $M=a_{1} \sqrt{n_{1}}+a_{2} \sqrt{n_{2}}+\cdots+a_{h} \sqrt{n_{h}} \in \mathbb{Z} \backslash\{0\}$. Summation of these two $M$ cancels $a_{1} \sqrt{n_{1}}$ and results in

$$
2 M=\left(a_{2} \pm a_{2}\right) \sqrt{n_{2}}+\left(a_{3} \pm a_{3}\right) \sqrt{n_{3}}+\cdots+\left(a_{h} \pm a_{h}\right) \sqrt{n_{h}},
$$

which contradicts to the induction hypothesis.

Proposition A.0.4. The set $\{\sqrt{n} \mid n \in \mathbb{N}$ is square-free $\}$ is linearly independent over rationals.

Proof. The proposition is equivalent to the following: Let $a_{i} \in \mathbb{Z}$ and let $n_{i}$ be different square-free numbers, where $1 \leq i \leq N$.

If $a_{1}, a_{2}, \cdots, a_{N}$ are not all zeros, then $a_{1} \sqrt{n_{1}}+a_{2} \sqrt{n_{2}}+\cdots+a_{N} \sqrt{n_{N}} \neq 0$.

Prove by induction on $N$. When $N=1$, it is clear. Assumption that $a_{1} \sqrt{n_{1}}+$ $a_{2} \sqrt{n_{2}}+\cdots+a_{h-1} \sqrt{n_{h-1}} \neq 0$. When $N=h$, assume on the contradiction that $a_{1} \sqrt{n_{1}}+a_{2} \sqrt{n_{2}}+\cdots+a_{h} \sqrt{n_{h}}=0$.

$$
\begin{aligned}
& a_{1} \sqrt{n_{1}}+a_{2} \sqrt{n_{2}}+\cdots+a_{h-1} \sqrt{n_{h-1}}=-a_{h} \sqrt{n_{h}} \\
& a_{1} \sqrt{n_{1} n_{h}}+a_{2} \sqrt{n_{2} n_{h}}+\cdots+a_{h-1} \sqrt{n_{h-1} n_{h}}=-a_{h} n_{h} \in \mathbb{Z} \backslash\{0\},
\end{aligned}
$$

which contradicts to the Proposition A.0.3.
