Performance Tests of CORN VARIETIES AND HYBRIDS, 1944

By JAMES S. BROOKS
Associate Agronomist, Corn

The 1944 Corn Performance Tests of the Oklahoma Agricultural Experiment Station were conducted at 14 locations scattered throughout the corn-growing section of the State (see map, page 7). A total of 126 hybrid strains and 16 open-pollinated varieties was grown in one or more of the tests. Locations were chosen to represent as nearly as possible the predominant soil types in the area where the test was grown.

The 1944 results are shown in the accompanying tables. *They leave little doubt as to the ability of certain hybrids to yield appreciably more grain than standard open-pollinated varieties.*

The results also indicate that soil type and seasonal conditions play an important part in determining which hybrid gives the best yield. In view of the variable seasonal conditions in this State, *it seems advisable to plant at least two hybrids of different maturity.* If unfavorable weather catches one hybrid at a critical period, the other may escape. The large number of hybrids on the market and the wide range of their maturity is advantageous in this respect.

Hybrids which have produced good yields at several test locations are the safest choice. Many farmers prefer the type and quality of grain produced by hybrids developed for neighboring states, therefore these hybrids are to be favored if their maturity is suited to the type of soil where they are to be planted.

There is need for good hybrids of early maturity adapted to this state, and *hybrids of this type are now being developed at the Oklahoma experiment station.*

Interpreting the Tables

Yield of each strain planted at the various test locations is given in Tables I to XVI. Tables XVII to XXII give summaries by soil types and for past years. Yields shown are bushels per acre, except in the popcorn tables where they are pounds per acre.

The yields reported in the tables are calculated as shelled corn containing 15.5 percent moisture, the upper limit allowable for No. 2 corn. An estimate of the variation in yield

which might be expected to result from variations in soil and other factors within the test field is given for each test location. *This "significant difference," shown at the top of each table, should be kept in mind whenever two strains are compared.*

Except where otherwise indicated, the yields reported in the tables are for 1944 and of course do not prove which strains will do best another season or at another location. A better estimate of the performance of a particular strain over a period of years and at a variety of locations can be had by observing the performance of that strain at several locations. Therefore the 1944 yields for several selected locations are summarized in Tables XVII to XIX (pages 22 to 24);* and yields at Stillwater and Perkins over a period of years are averaged in Tables XX to XII (pages 25 and 26).

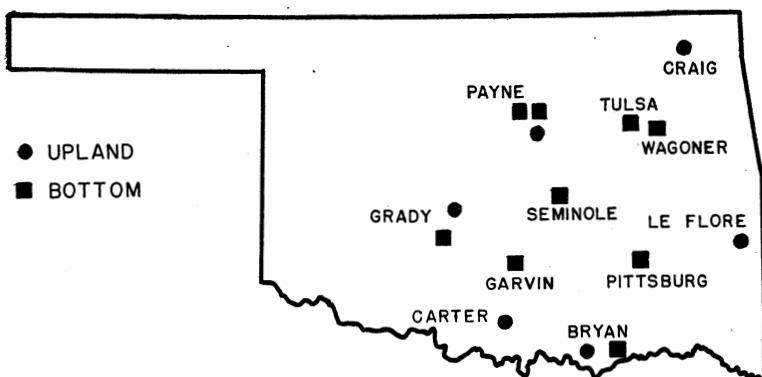

Hybrids developed by experiment stations of neighboring states made very good records, probably partly due to a better adaptation to soil and climatic conditions. The two Kansas hybrids 1583 and 2234 (white) are in all three summary lists. Texas hybrids 12 and 7W (white) and Kansas 1585 are in both bottomland lists. U. S. 13, which is widely planted in the southern half of the Corn Belt, is in the upland and one bottomland list.

That upland needs an earlier maturing strain than is suited to fertile bottomland is indicated by the strains which appear in the three 1944 summary lists. The average silk date** for all strains listed in the summary table for the bottomland of high fertility is 32.6 (July 3; see following paragraph). For the medium fertile bottomlands it is 30.0 (June 30); and for uplands 28.8 (June 29). This is in agreement with results over a period of years at the Stillwater and Perkins farms.

SILK DATE.—The silk date recorded in some of the tables is the number of days after June 1 required for 50 percent of the plants to show silk. That is, "27" indicates June 27; "34"

* The table summarizing yields for bottomlands of high fertility includes the Garvin county and Seminole county tests where the season was very favorable, the Wagoner county tests where conditions were moderately favorable, and the Bryan county test where yields were limited by dry weather in late June and July. These four tests therefore should give a much more accurate index to performance than any single test on the more fertile soils. Every strain recorded in that table and in the similar table for upland tests has been in at least two tests and has at least once yielded 1½ times (150 percent) the average of the five open-pollinated varieties used as a check. In the table summarizing bottomland tests of medium fertility, strains were included if they yielded 1½ times (133 percent) the check at one or more locations. The Tulsa county test was included in this group since it was planted mainly to earlier maturing strains in order to permit early harvest and allow other experiments on the same land.

** As recorded in the Stillwater tests.

Where 1944 Corn Performance Tests Were Made.

A total of 126 hybrid strains and 16 open-pollinated varieties was grown at one or more of the plots shown on the above map. At most locations, 49 strains and varieties were tested. Tests are scattered throughout the corn-growing section of the state to give an indication of which hybrids are adapted to the various types of soil and climatic conditions.

indicates July 4 (34-30 days in June-July 4); etc. Silk date is one of the more accurate measures of maturity. For two strains planted at the same time and on the same soil, each day's difference in silk date will indicate two to three days' difference in maturity.

PLANT SPACING AND SEED BED PREPARATION.—The test plots were prepared for planting by the cooperating farmer in the same way he prepared his own corn field, which in all cases was the usual seed bed preparation for corn. The plots were hand planted in hills 42 inches apart in the row and three grains per hill.* At some locations this produced a stand thicker than desirable for maximum production and quality of grain, but should not affect comparison between strains. The plots were not thinned and the only correction of yields for variation in stand was an adjustment for missing hills.

LODGED PLANTS.—Percent of lodged plants is shown in the tables wherever lodging was sufficient to appear indicative of differences between strains. Plants were considered lodged when they were leaning more than 30 degrees from the vertical or if the stalks were broken below the ear.

* Row widths varied from 38 to 42 inches, depending upon that used by the particular cooperator.

INDIVIDUAL TESTS

Yields in Bushels Per Acre

TABLE I—BRYAN COUNTY (Upland)
J. T. Caddel Farm; Calera, 3 miles southwest

A difference of less than 4.7 bushels per acre between any two strains should not be considered significant in this test.
