# AN APPROACH TO MODELLING THE COEFFICIENT 

## OF VARIATION IN FACTORIAL EXPERIMENTS

By

## CRAIG ALAN WILSON

Bachelor of Science
Oklahoma State University
Stillwater, Oklahoma 1992

Master of Science
Oklahoma State University
Stillwater, Oklahoma 1994

Submitted to the Faculty of the Graduate College of the Oklahoma State University in partial fulfillment of the requirements for the Degree of
DOCTOR OF PHILOSOPHY
May, 1998

Thesis

## AN APPROACH TO MODELLING THE COEFFICIENT

 OF VARIATION IN FACTORIAL EXPERIMENTSThesis Approved:

## ACKNOWLEDGMENTS

As I close this phase of my academic career, I am reminded of the countless individuals who, over the years, have given that small word of encouragement or provided that boost that kept me going.

I cannot express in words how important my wife, Faith, has been to me. She has been my companion not only at home but also in school as we have pursued our doctoral degrees together. The past four years with her at Oklahoma State have been the most wonderful of my life and I will never forget them.

I want to thank my father and step-mother, Delbert and Susan Wilson, and my mother and step-father, Sharon and Tommy Whitmire, for their understanding, assistance, and love. Without them, my academic career would never have begun.

My sincere gratitude also goes to my adviser, Dr. Mark E. Payton. He has been so much more than an adviser -- he has also been a close friend. His confidence in me has been more uplifting than I can convey. Additionally, I wish to acknowledge the other members of my committee, Dr. P. Larry Claypool, Dr. William D. Warde, and Dr. Kenneth E. Case, for their insight and encouragement throughout this process.

As a boy, I could never, in my wildest dreams, have imagined that I would someday receive a Ph.D. To those named and unnamed who have had a part in making this a reality, I will always be thankful.

## TABLE OF CONTENTS

Chapter Page
I. INTRODUCTION ..... 1
II. REVIEW OF LITERATURE ..... 4
Terminology and Definitions ..... 4
Approximate Distributions of the Sample CV ..... 5
McKay's and David's Approximations ..... 6
Iglewicz and Myers' Approximation ..... 7
Comparisons to Exact Quantiles ..... 7
One-Factor Tests for Population CVs ..... 18
Bennett's and Shafer and Sullivan's Tests ..... 18
Doornbos and Dijkstra's Likelihood-Ratio Test ..... 19
Doornbos and Dijkstra's Non-Central t Test ..... 22
Gupta and Ma's Wald Test ..... 24
Gupta and Ma's Score Test ..... 26
Feltz and Miller's Test ..... 28
Factorial Designs for Population CVs ..... 29
The Taguchi Approach ..... 29
Bissell's Approach ..... 30
Zacks' Approach ..... 32
III. REVIEW OF THEORY ..... 33
The Exponential Family ..... 33
Maximum-Likelihood Estimation ..... 35
The Newton-Raphson Algorithm ..... 36
The Fisher Scoring Algorithm ..... 37
Alternate Step Lengths ..... 37
Quasi-Likelihood Estimation ..... 38
Asymptotic Properties of the Maximum- and Quasi- Likelihood Estimators ..... 41
The Generalized Linear Model ..... 42
Model Diagnostics ..... 46
The Wald Test ..... 46
The Likelihood-Ratio Test ..... 47
The Score Test ..... 49
Tests for the Saturated Model ..... 50
IV. THE MODELLING APPROACH ..... 51
Choice of Model ..... 51
The Model-Fitting Algorithm ..... 54
McKay's and David's Approximations ..... 55
Iglewicz and Myers' Approximation ..... 57
Existence and Uniqueness of Estimators ..... 59
Model Selection ..... 60
Additive Models for Population CVs ..... 61
McKay's and David's Approximations ..... 62
Iglewicz and Myers' Approximation ..... 63
Existent One-Factor Tests as Special Cases ..... 63
Shafer and Sullivan's Test ..... 63
Gupta and Ma's Wald Test ..... 64
Feltz and Miller's Test ..... 66
Confidence Intervals for Fitted Models ..... 67
V. SIMULATION METHODS AND RESULTS ..... 70
Simulation Objectives ..... 70
Asymptotic Behavior of the Scaled Deviance ..... 70
Asymptotic Behavior of a Difference of Scaled Deviances ..... 70
Relative Capabilities of Model Diagnostics ..... 71
The One-Factor Experiment ..... 71
Non-Normal Data ..... 72
Simulation of a $2 \times 2$ Factorial Experiment ..... 72
Simulation of a One-Factor Experiment ..... 73
Simulation of Non-Normal Data ..... 75
Simulation Results ..... 75
The Interaction Test ..... 75
The Main-Effect Test ..... 76
Relative Capabilities of Model Diagnostics ..... 77
The One-Factor Experiment ..... 78
The Interaction Test for Non-Normal Data ..... 79
Recommendations ..... 80
VI. APPLIED EXAMPLES ..... 82
Applied Example \#1 ..... 82
Applied Example \#2 ..... 87
Chapter Page
VII. CONCLUSION ..... 92
BIBLIOGRAPHY ..... 95
APPENDIXES ..... 99
APPENDIX A--TABLES OF SIMULATION RESULTS ..... 100
APPENDIX B--SAS PROGRAM TO CALCULATE EXACT AND APPROXIMATE QUANTILES ..... 212
APPENDIX C--SAS PROGRAM TO SIMULATE THE INTERACTION TEST ..... 214
APPENDIX D--SAS PROGRAM TO SIMULATE THE MAIN-EFFECT TEST ..... 220
APPENDIX E--SAS PROGRAM TO SIMULATE THE ONE-FACTOR TEST ..... 227
APPENDIX F--SAS CODE TO GENERATE GAMMA- DISTRIBUTED DATA FOR THE INTERACTION TEST ..... 234

## LIST OF TABLES

Table Page
I. Exact and Approximate Quantiles of the Distribution of $r$ and $r_{n}$ for $\mathrm{R}=0.1$ and $\mathrm{n}=10$ ..... 9
II. Exact and Approximate Quantiles of the Distribution of $r$ and $r_{n}$ for $R=0.1$ and $\mathrm{n}=50$ ..... 10
III. Exact and Approximate Quantiles of the Distribution of $r$ and $r_{n}$ for $\mathbf{R}=0.1$ and $\mathrm{n}=100$ ..... 11
IV. Exact and Approximate Quantiles of the Distribution of $r$ and $r_{n}$ for $\mathbf{R}=0.2$ and $\mathrm{n}=10$ ..... 12
V. Exact and Approximate Quantiles of the Distribution of r and $\mathrm{r}_{\mathrm{n}}$ for $\mathrm{R}=0.2$ and $\mathrm{n}=50$ ..... 13
VI. Exact and Approximate Quantiles of the Distribution of $r$ and $r_{n}$ for $\mathbf{R}=0.2$ and $\mathrm{n}=100$ ..... 14
VII. Exact and Approximate Quantiles of the Distribution of r and $\mathrm{r}_{\mathrm{n}}$ for $\mathbf{R}=0.33$ and $\mathbf{n}=10$ ..... 15
VIII. Exact and Approximate Quantiles of the Distribution of r and $\mathrm{r}_{\mathrm{n}}$ for $\mathrm{R}=0.33$ and $\mathrm{n}=50$ ..... 16
IX. Exact and Approximate Quantiles of the Distribution of r and $\mathrm{r}_{\mathrm{n}}$ for $\mathbf{R}=0.33$ and $\mathrm{n}=100$ ..... 17
X. Observed Means, Standard Deviations, and CVs of Log-Duck-Kills (Base 10) Per Hunter by Province and Year ..... 84
XI. Estimated Parameters for Saturated Model of CVs of Log-Duck-Kills (Base 10) Per Hunter ..... 84
XII. Asymptotic 95\% Confidence Intervals for Log-Ratio and Ratio of CVs of Log-Duck-Kills (Base 10) Per Hunter (1969 to 1970) by Province ..... 86
XIII. Observed Means, Standard Deviations, and CVs of pH Levels by Temperature and Lab ..... 88
XIV. Estimated Parameters for Lab Model of CVs of pH Levels ..... 90
XV. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{1 0}$ ..... 101
XVI. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{2 0}$ ..... 102
XVII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{3 0}$103XVIII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{5 0}$104
XIX. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{22}=10, \mathbf{n}_{12}=\mathbf{n}_{21}=20$ ..... 105
XX. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{22}=20, \mathbf{n}_{12}=\mathbf{n}_{21}=10$106
XXI. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{12}=20, \mathbf{n}_{21}=\mathbf{n}_{22}=10$107
XXII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{22}=20, \mathbf{n}_{12}=\mathbf{n}_{21}=30$108
XXIII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{22}=30, \mathbf{n}_{12}=\mathbf{n}_{21}=20$109
XXIV. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,$\mathbf{n}_{11}=\mathbf{n}_{12}=30, \mathbf{n}_{21}=\mathbf{n}_{22}=20$110
XXV. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{22}=10, \mathbf{n}_{12}=\mathbf{n}_{21}=30$.111
XXVI. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{22}=30, \mathbf{n}_{12}=\mathbf{n}_{21}=10$112
XXVII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=30, \mathbf{n}_{21}=\mathbf{n}_{22}=10$113
XXVIII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,
$\mathbf{n}_{11}=\mathbf{n}_{22}=30, \mathbf{n}_{12}=\mathbf{n}_{21}=50$
XXIX. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{22}=\mathbf{5 0}, \mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{3 0}$
XXX. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=50, \mathbf{n}_{21}=\mathbf{n}_{22}=30$
XXXI. Rejection Rates for Interaction Test at $\alpha=0.05$ for $O$ verall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=30$
XXXII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=50$118
XXXIII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=100$119
XXXIV. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{22}=30, \mathbf{n}_{12}=\mathbf{n}_{21}=50$120
XXXV. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{22}=50, \mathbf{n}_{12}=\mathbf{n}_{21}=30$121
XXXVI. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=50, \mathbf{n}_{21}=\mathbf{n}_{22}=30$122
XXXVII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{22}=50, \mathbf{n}_{12}=\mathbf{n}_{21}=100$123
XXXVIII. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{22}=100, \mathbf{n}_{12}=\mathbf{n}_{21}=50$124
XXXIX. Rejection Rates for Interaction Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=100, \mathbf{n}_{21}=\mathbf{n}_{22}=50$125
XL. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,

$$
\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=10
$$126

XLI. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,

$$
\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=20
$$ ..... 127

XLII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,
$\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=30 \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots$
XLIII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=50$129
XLIV. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=10, \mathbf{n}_{12}=\mathbf{n}_{22}=20$130
XLV. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for $O v e r a l l$ R $=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=20, \mathbf{n}_{12}=\mathbf{n}_{22}=10$131
XLVI. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=20, \mathbf{n}_{21}=\mathbf{n}_{22}=10$.132
XLVII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=20, \mathbf{n}_{12}=\mathbf{n}_{22}=30$133
XLVIII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=30, \mathbf{n}_{12}=\mathbf{n}_{22}=20$134
XLIX. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=30, \mathbf{n}_{21}=\mathbf{n}_{22}=20$ 135
L. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=10, \mathbf{n}_{12}=\mathbf{n}_{22}=30$ 136
LI. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{21}=30, \mathbf{n}_{12}=\mathbf{n}_{22}=10$ 137
LII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $R=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=30, \mathbf{n}_{21}=\mathbf{n}_{22}=10$ 138
LIII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathrm{n}_{11}=\mathrm{n}_{21}=30, \mathbf{n}_{12}=\mathbf{n}_{22}=50$ 139
LIV. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathrm{n}_{11}=\mathrm{n}_{21}=50, \mathrm{n}_{12}=\mathrm{n}_{22}=30$ 140
LV. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$, $\mathbf{n}_{11}=\mathbf{n}_{12}=50, \mathbf{n}_{21}=\mathbf{n}_{22}=30$

> LVI. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{3 0}$
LVII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{5 0}$143

LVIII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.2$,
$\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{n}_{21}=\mathbf{n}_{22}=100$ ..... 144
LIX. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{21}=30, \mathbf{n}_{12}=\mathbf{n}_{22}=50$145
LX. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{21}=50, \mathbf{n}_{12}=\mathbf{n}_{22}=30$146

LXI. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$,
$\mathbf{n}_{11}=\mathbf{n}_{12}=\mathbf{5 0}, \mathbf{n}_{21}=\mathbf{n}_{22}=\mathbf{3 0}$ ..... 147
LXII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$, $\mathbf{n}_{11}=\mathbf{n}_{21}=50, \mathbf{n}_{12}=\mathbf{n}_{22}=100$.148

LXIII. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$,
$\mathbf{n}_{11}=\mathbf{n}_{21}=100, \mathbf{n}_{12}=\mathbf{n}_{22}=50$ ..... 149

LXIV. Rejection Rates for Main-Effect Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.2$,
$\mathbf{n}_{11}=\mathbf{n}_{12}=100, \mathbf{n}_{21}=\mathbf{n}_{22}=50$ ..... 150
LXV. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=\mathbf{n}_{2}=\mathbf{n}_{\mathbf{3}}=10$151

LXVI. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathrm{R}=0.1$,
$\mathbf{n}_{1}=\mathbf{n}_{2}=\mathbf{n}_{\mathbf{3}}=\mathbf{2 0}$ ..... 152
LXVII. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=\mathbf{n}_{2}=\mathbf{n}_{\mathbf{3}}=\mathbf{3 0}$153

LXVIII. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$,
$\mathbf{n}_{1}=\mathbf{n}_{2}=\mathbf{n}_{\mathbf{3}}=50$ ..... 154
LXIX. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=10, \mathbf{n}_{2}=\mathbf{n}_{3}=20$ ..... 155

> LXX. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=20, \mathbf{n}_{2}=10, \mathbf{n}_{3}=20$
LXXI. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=\mathbf{n}_{2}=20, \mathbf{n}_{3}=10$157
LXXII. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=\mathbf{n}_{2}=10, \mathbf{n}_{3}=20$158
LXXIII. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=10, \mathbf{n}_{2}=20, \mathrm{n}_{3}=10$159
LXXIV. Rejection Rates for One-Factor Test at $\alpha=0.05$ for Overall $\mathbf{R}=0.1$, $\mathbf{n}_{1}=20, \mathbf{n}_{2}=\mathbf{n}_{3}=10$ 160

## CHAPTER ONE

## INTRODUCTION

As the ratio of the sample standard deviation to the sample mean, the sample coefficient of variation (CV) provides a useful and unitless measure of relative variability. As Ahmed (1994) notes, the CV can sometimes be more relevant than the standard deviation alone, such as when the precision of measuring instruments or the volatility of stocks is considered. Hurlimann (1995) points out that the CV is useful in insurance risk assessment as a measure of the heterogeneity of insurance portfolios. Williams (1991) cites the importance of the CV in the determination of detection limits in instrumental analysis. Feltz and Miller (1996) notes that in medical studies, the CV often determines the feasibility of combining results from separate clinical trials.

Payton (1997) suggests that the types of populations for which the CV has relevance are those which are of the ratio type. In such populations, an observation equal to zero represents the absence of the measured characteristic, such as with populations of volumes, yields, or weights, since only in this context does the CV ratio itself have meaning. Negative observations are not possible.

Although theoretically not of the ratio type, normal populations have long been considered in connection with the behavior of sample CVs. In such cases, negative sample means are assumed to be highly improbable. However, in contrast with the mean of the
normal distribution, comparatively little work has been done in connection with hypothesis tests and confidence intervals for unknown population CVs based on observed data. Papers which have addressed these subjects for a single population CV include Koopmans, et al. (1964), Vangel (1996), and Payton (1997), which utilize exact and approximate distributions of the sample CV from a normal population. Tests for the equality of $k$ normal population CVs that employ approximate distributions and the normal density include Bennett (1976), Miller and Karson (1977), Doornbos and Dijkstra (1983), and Shafer and Sullivan (1986). Gupta and Ma (1996) extends a Wald test developed by Rao and Vidya (1992) for two populations based on the normal density to k populations and introduces a score test which also utilizes the actual density of the observations. A test based on the asymptotic moments of the CV is provided by Feltz and Miller (1996).

Less work has addressed the analysis of population CVs in the context of designed factorial experiments. Taguchi (1992) discusses a well-known approach to the analysis of product quality using fractional factorial designs that often models a log-transformed CV. However, his approach has yielded recent criticisms (see, for example, Box, 1988) and corrections because of biased tests of factor effects. More recent work by McCullagh and Nelder (1989) and Nelder and Lee (1991) has utilized models of the CVs of gamma populations within a larger theory of joint modelling of mean and dispersion in designed industrial experiments. An alternative approach to modelling the CVs of gamma distributions from a sociological standpoint is provided by Eliason (1993).

Absent from the current literature, however, is a technique for constructing factorial models of the CVs of normal populations that makes use of known approximate distributions and asymptotic moments of the sample CV. The current work addresses this
situation by first establishing a proper structure for a model of population CVs in a general setting. Next, the theory of generalized linear modelling is applied in the context of maximum- and quasi-likelihood estimation to achieve a simplified iterative algorithm for estimation of model parameters that parallels methods currently used to fit models in categorical data analysis. An application of model diagnostics like those used in categorical analysis is proposed, and simulations to investigate the power of these diagnostics in the context of the approximate distributions and asymptotic moments are discussed. The effects of departures from the normal assumption also are determined.

## CHAPTER TWO

## REVIEW OF LITERATURE

In this chapter, several approximations to the exact distribution of the sample CV when data are drawn from a normal population are discussed, and comparisons to the exact distribution are made. Several one-factor tests for the equality of $k$ normal population CVs currently in the literature are reviewed, and variations of the Taguchi approach, which often implicitly models a log-transformed CV in a (fractional) factorial design, are summarized.

## Terminology and Definitions

Let $X_{1}, X_{2}, \ldots, X_{n}$ be a random sample from a normal population with $E\left(X_{i}\right)=$ $\mu>0$ and $\operatorname{Var}\left(X_{i}\right)=\sigma^{2}, i=1,2, \ldots, n$, and let $R=\sigma / \mu$ be the population $C V$. Define $\bar{X}=\sum_{i=1}^{n} X_{i} / n$ to be the sample mean and assume that $P(\bar{X}<0)$ is negligible. Let $S^{2}=$ $\sum_{\mathrm{i}=1}^{\mathrm{n}}\left(\mathrm{X}_{\mathrm{i}}-\overline{\mathrm{X}}\right)^{2} /(\mathrm{n}-1)$ and $\mathrm{S}_{\mathrm{n}}^{2}=\sum_{\mathrm{i}=1}^{\mathrm{n}}\left(\mathrm{X}_{\mathrm{i}}-\overline{\mathrm{X}}\right)^{2} / \mathrm{n}$ be the unbiased and maximumlikelihood estimates of $\sigma^{2}$, respectively, and let $r=S / \bar{X}$ and $r_{n}=S_{n} / \bar{X}$ be the corresponding point estimates of $R$. Note that $r_{n}$ is the maximum-likelihood estimate of $R$ and that $r_{n}=((n-1) / n)^{1 / 2} r$. Although neither $r$ nor $r_{n}$ is an unbiased estimate of $R$, both
are strongly consistent; that is, $P\left(\lim _{n \rightarrow \infty} r=R\right)=P\left(\lim _{n \rightarrow \infty} r_{n}=R\right)=1$ (Serfling, 1980, pp. 2426, 136-137). Hence, both are reasonable estimators of $R$, particularly when computed from large samples.

For later convenience, define the $h$-function $h(x)=x^{2} /\left(1+x^{2}\right)$ for $x>0$. Then $h$ has an inverse, and $h^{-1}(x)=(x /(1-x))^{1 / 2}$ for $0<x<1$. Additionally, define a random variable $Y$ to have the gamma distribution with parameters $\lambda$ and $v$ if and only if its density is given by

$$
\begin{aligned}
f(y) & =\frac{1}{y \Gamma(v)}\left(\frac{v y}{\lambda}\right)^{v} \exp \left(-\frac{v y}{\lambda}\right), \quad y \geq 0 \\
& =0, \quad y<0,
\end{aligned}
$$

where $\lambda>0, v>0$, and $\Gamma(\bullet)$ is the gamma function. It follows that $\mathrm{E}(\mathrm{Y})=\lambda$ and $\operatorname{Var}(\mathrm{Y})$ $=\lambda^{2} / v$. The parameter $v$ is sometimes called the index (McCullagh and Nelder, 1989, p. 287).

## Approximate Distributions of the Sample CV

Under normal theory, the exact distribution of $r$ is a multiple $(\sqrt{n})$ of the inverse of a non-central $t$ distribution having $(n-1)$ degrees of freedom and non-centrality parameter $\sqrt{n} / R$. The density of the non-central $t$ for degrees of freedom $p$ and noncentrality parameter $q$ is given by Lehmann (1959, p. 200) as

$$
\begin{equation*}
f(t)=\left(2^{(p+1) / 2} \Gamma(p / 2)(\pi p)^{1 / 2}\right)^{-1} \int_{0}^{\infty} y^{(p-1) / 2} \exp \left[-\frac{y}{2}-\frac{1}{2}\left(t \sqrt{\frac{y}{p}}-q\right)^{2}\right] d y \tag{2.1}
\end{equation*}
$$

for $-\infty<t<\infty$. Given the density of $r$, the density of $r_{n}$ can be obtained, in turn, by transforming $\mathbf{r}$ according to $\mathbf{r}_{\mathrm{n}}=((\mathrm{n}-1) / \mathbf{n})^{1 / 2} \mathbf{r}$. Difficulties associated with direct application of the non-central $t$ distribution itself have prompted the study of several approximations to the exact distributions of $r$ and $r_{n}$.

## McKay's and David's Approximations

McKay (1932) gives the earliest approximation to the distribution of $r_{n}$ when samples are drawn from a normal population. By utilizing a contour-integral expression of the density of $r_{n}$, he is able to show that $n h\left(r_{n}\right) / h(R)$ has an approximate $\chi^{2}$ distribution with ( $n-1$ ) degrees of freedom, provided that $R \in(0,1 / 3)$. This requirement on $R$ is consistent with the added assumption that negative observations also are highly improbable, in addition to a negative sample mean. Equivalently, $(n /(n-1)) h\left(r_{n}\right)$ has an approximate gamma distribution with expectation $h(R)$ and index $(n-1) / 2$. Vangel (1996) observes that McKay utilizes an asymptotic approximation in his derivation, so that his approximation is, in fact, most accurate for large $n$, although its small sample properties also are very good.

David (1949) obtains an approximation to the distribution of $r$ by reexpressing McKay's approximation in terms of r and deleting a negligible term. Beginning with $\mathbf{n h}\left(\mathbf{r}_{\mathrm{n}}\right) / \mathrm{h}(\mathrm{R})$, she writes

$$
\frac{\operatorname{nh}\left(r_{n}\right)}{h(R)}=\frac{n}{h(R)} \frac{r_{n}^{2}}{1+r_{n}^{2}}=\frac{n}{h(R)} \frac{\left(\frac{n-1}{n}\right) r^{2}}{1+\left(\frac{n-1}{n}\right) r^{2}}
$$

$$
=\frac{n-1}{h(R)} \frac{r^{2}}{1+r^{2}-\frac{r^{2}}{n}} \approx \frac{n-1}{h(R)} \frac{r^{2}}{1+r^{2}}=\frac{(n-1) h(r)}{h(R)}
$$

since $r^{2} / n$ is typically close to zero for large $n$. She thus obtains that $(n-1) h(r) / h(R)$ also has an approximate $\chi^{2}$ distribution with ( $n-1$ ) degrees of freedom, or, equivalently, that $h(r)$ is distributed approximately gamma with expectation $h(R)$ and index $(n-1) / 2$. Iglewicz and Myers' Approximation

A third approximation for consideration is discussed by Iglewicz and Myers (1970). They derive asymptotic expansions for the moments of the exact distribution of $r$ under normal theory and conclude that an adequate approximation for even relatively small $n$ can be obtained by assuming that $r$ itself is normally distributed with mean $R$ and variance $\left(\frac{R^{2}}{n}\right)\left(R^{2}+\frac{1}{2}\right)$. This variance was apparently given originally by Pearson (David, 1949). Both Serfling (1980, pp. 136-137) and Feltz and Miller (1996) note that r is, in fact, asymptotically normal with these same moments. Hence, an application of Slutsky's Theorem gives that $\mathrm{r}_{\mathrm{n}}$ likewise possesses these asymptotic properties (Serfling, p. 19). Simulation results reported by Iglewicz and Myers suggest that this approximation is superior to other normal approximations with higher-order expansions for the mean and variance.

## Comparisons to Exact Quantiles

Owen (1968) outlines a process to determine cumulative probabilities of the exact distribution of $r$ based on the non-central $t$ distribution. Making use of (2.1), he notes
that, for $\mathrm{c}>0$,

$$
\begin{aligned}
P(r>c) & =P\left(\frac{S}{\bar{X}}>c\right)=P\left(0<\frac{\overline{\mathbf{X}}}{S}<\frac{1}{c}\right)=P\left(0<\frac{\sqrt{n} \bar{X}}{S}<\frac{\sqrt{n}}{c}\right) \\
& =P\left(0<t<\frac{\sqrt{n}}{c}\right)
\end{aligned}
$$

where $t$ has the non-central $t$ distribution with ( $n-1$ ) degrees of freedom and noncentrality parameter $\sqrt{\mathrm{n}} / \mathrm{R}$. Hence,

$$
\begin{equation*}
P(\mathrm{r}<\mathrm{c})=\mathrm{P}(\mathrm{t}<0)+\mathrm{P}\left(\mathrm{t}>\frac{\sqrt{\mathrm{n}}}{\mathrm{c}}\right) . \tag{2.2}
\end{equation*}
$$

Using (2.2), exact quantiles can be computed for $r$, from which quantiles for $r_{n}$ can be obtained using $r_{n}=((n-1) / n)^{1 / 2} r$. Tables I through IX give selected exact quantiles for $r$ and $r_{n}$, as well as corresponding quantiles for each of the approximate distributions discussed above. The SAS program used to calculate these quantiles is included in Appendix B.

The tables suggest that both McKay's and David's approximations perform very well, especially for smaller values of R and for large $\mathbf{n}$. Iglewicz and Myers' approximation generally performs worse than David's approximation but improves for large n . All three approximations are less accurate as R increases. There is a clear disparity between Iglewicz and Myers' approximation and the exact distribution of $r$ near the first and third quartiles, particularly for small n. David (1949) comments that the normal approximation to the distribution of $r$ works best for values of $n>40$.

## One-Factor Tests for Population CVs

Suppose $X_{i 1}, X_{i 2}, \ldots, X_{i n_{1}}, i=1,2, \ldots, k$ are independent random samples from $k$ normal populations having $\mathrm{E}\left(\mathrm{X}_{\mathrm{ij}}\right)=\mu_{\mathrm{i}}>0, \operatorname{Var}\left(\mathrm{X}_{\mathrm{ij}}\right)=\sigma_{\mathrm{i}}^{2}$, and $\mathbf{C V s} \mathrm{R}_{\mathrm{i}}=\sigma_{\mathrm{i}} / \mu_{\mathrm{i}}$. Assume $P\left(\bar{X}_{i}<0\right)$ is negligible for all i. Let $S_{i}^{2}$ and $S_{n, i}^{2}$ be the unbiased and maximum-likelihood estimates of $\sigma_{i}^{2}$, respectively, and let $r_{i}=S_{i} / \bar{X}_{i}$ and $r_{n, i}=S_{n, i} / \bar{X}_{i}$ be the corresponding point estimates of $\mathbf{R}_{i}$.

## Bennett's and Shafer and Sullivan's Tests

Bennett (1976) proposes a procedure for testing $H_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{k}$ that makes apparent use of McKay's approximation for $r_{n}$. He notes that since $h\left(R_{i}\right)$ is a monotone function of $R_{i}$, then the null hypothesis $H_{o}^{\prime}: h\left(R_{1}\right)=h\left(R_{2}\right)=\ldots=h\left(R_{k}\right)$ is equivalent to $H_{o}$ and corresponds to a test of the equality of means of k gamma distributions, since $\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{n, i}\right)$ is distributed approximately gamma with expectation $h\left(R_{i}\right)$ and index $\left(n_{i}-1\right) / 2$ according to McKay (1932).

Under this distributional assumption and hypothesis, Bennett applies a likelihoodratio statistic suggested by Pitman (1939) and obtains

$$
\begin{equation*}
(N-k) \log \sum_{i=1}^{k}\left(n_{i} h\left(r_{i}\right) /(N-k)\right)-\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(n_{i} h\left(r_{i}\right) /\left(n_{i}-1\right)\right), \tag{2.3}
\end{equation*}
$$

where $\mathrm{N}=\sum_{\mathrm{i}} \mathrm{n}_{\mathrm{i}}$, which, he argues, is approximately distributed $\chi^{2}$ with $(\mathrm{k}-1)$ degrees of freedom under $\mathrm{H}_{0}^{\prime}$.

However, Bennett makes the erroneous assumption that McKay's approximation applies to $r_{i}$, not $r_{n, i}$, as McKay intended. That is, Bennett assumes that $\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{i}\right)$ is distributed approximately gamma with mean $h\left(\mathbf{R}_{i}\right)$ and index $\left(\mathbf{n}_{i}-1\right) / 2$, or, equivalently, that $n_{i} h\left(r_{i}\right) / h\left(R_{i}\right)$ is approximately distributed $\chi^{2}$ with $\left(n_{i}-1\right)$ degrees of freedom, which is a slightly less accurate approximation to the distribution of $r_{i}$ than McKay's approximation is of $\mathrm{r}_{\mathrm{n}, \mathrm{i}}$ (Umphrey, 1983). Curiously, Warren (1982) also makes this mistake in a paper documenting apparent discrepancies between McKay's approximation and the exact distribution of $r$.

This fact led Shafer and Sullivan (1986) to investigate the effect of replacing $h\left(r_{i}\right)$ by the more appropriate $h\left(\mathrm{r}_{\mathrm{n}, \mathrm{i}}\right)$ in (2.3). They find a slight increase in power, but recommend Bennett's test since it employs a more familiar form of the sample CV. Doornbos and Dijkstra's Likelihood-Ratio Test

Doornbos and Dijkstra (1983) proposes a likelihood-ratio test for the equality of $k$ normal population CVs that utilizes a reparameterized normal density and extends an earlier procedure by Miller and Karson (1977), which deals only with two populations and equal sample sizes. Doornbos and Dijkstra substitute $\frac{\sigma_{i}}{R_{i}}$ for $\mu_{i}$ in the density (since $R_{i}=$ $\sigma_{i} / \mu_{i}$ ) and solve their chosen likelihood equations in $R^{-1}$ and $\sigma_{i}, i=1,2, \ldots, k$ under the null hypothesis $\mathrm{H}_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{\mathrm{k}}=\mathbf{R}$ (unknown). However, Doornbos and Dijkstra offer an iterative algorithm for solving these equations which Gupta and Ma (1996) calls "questionable". In response, Gupta and Ma provide an alternative reparameterization,
substituting $\mathbf{R}_{\mathrm{i}} \mu_{\mathrm{i}}$ for $\sigma_{\mathrm{i}}$, and suggest an improved algorithm for solving the resulting likelihood equations.

Under $H_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{\mathrm{k}}=\mathbf{R}$ (unknown), using Gupta and Ma's parameterization, the $\log$-likelihood is given by $L_{o}=-\sum_{i=1}^{k} n_{i} \log \left((2 \pi)^{1 / 2} \mu_{i} R\right)-$ $\sum_{i=1}^{k} \sum_{\mathrm{j}=1}^{\mathrm{n}_{\mathrm{i}}} \frac{\left(\mathrm{X}_{\mathrm{ij}}-\mu_{\mathrm{i}}\right)^{2}}{2 \mu_{\mathrm{i}}^{2} \mathrm{R}^{2}}$. Differentiating with respect to R and $\mu_{\mathrm{i}}$ gives the likelihood equations

$$
\begin{aligned}
& \frac{\partial L_{0}}{\partial R}=-\sum_{i=1}^{k} \frac{n_{i}}{R}+\sum_{i=1}^{k} \sum_{j=1}^{n_{i}} \frac{\left(X_{i j}-\mu_{i}\right)^{2}}{2 \mu_{i}^{2} R^{3}}=0, \text { and } \\
& \frac{\partial L_{0}}{\partial \mu_{i}}=-\frac{n_{i}}{\mu_{i}}+\sum_{j=1}^{n_{i}} \frac{X_{i j}\left(X_{i j}-\mu_{i}\right)}{\mu_{i}^{3} R^{2}}=0, i=1,2, \ldots, k .
\end{aligned}
$$

Simplifying the equations gives

$$
\begin{align*}
& \sum_{i=1}^{k} \frac{n_{i}\left(1+\sqrt{1+4\left(1+r_{i}^{2}\right) R^{2}}\right)}{2\left(1+r_{i}^{2}\right)}-\sum_{i=1}^{k} n_{i}=0, \text { and }  \tag{2.4}\\
& \mu_{i}=\frac{2\left(1+r_{i}^{2}\right) \bar{X}_{i}}{1+\sqrt{1+4\left(1+r_{i}^{2}\right) R^{2}}}, i=1,2, \ldots, k \tag{2.5}
\end{align*}
$$

Equation (2.4) has no closed form solution in R for $\mathrm{k}>2$ and requires an iterative solution.

Using Gupta and Ma's algorithm, let $m=\min \left\{\mathbf{r}_{1}, \mathrm{r}_{2}, \ldots, \mathrm{r}_{\mathrm{k}}\right\}$ and $\mathbf{M}=\max \left\{\mathbf{r}_{1}, \mathbf{r}_{2}, \ldots\right.$, $\left.r_{k}\right\}$. Let $G(R)$ equal the left-hand side of (2.4). Then $G(m) \leq 0 \leq G(M)$, so that the solution is in the interval [ $\mathrm{m}, \mathrm{M}$ ]. Bisecting [ $\mathrm{m}, \mathrm{M}$ ], the solution falls into the half having left endpoint $m_{1}$ satisfying $G\left(m_{1}\right) \leq 0$ and right endpoint $M_{1}$ satisfying $G\left(M_{1}\right) \geq 0$. Bisecting [ $\mathrm{m}_{1}, \mathrm{M}_{1}$ ] in turn, the solution now falls into the half having left endpoint $\mathrm{m}_{2}$
satisfying $G\left(m_{2}\right) \leq 0$ and right endpoint $M_{2}$ satisfying $G\left(M_{2}\right) \geq 0$. The process is continued until, at the $t^{\text {th }}$ iteration, the bisection point $\left(m_{t}+M_{t}\right) / 2$ gives $G\left(\left(m_{t}+M_{t}\right) / 2\right)$ sufficiently close to zero.

Denoting the resulting approximate solution by $\widetilde{\mathbf{R}}$, the value may be substituted into (2.5) to obtain the restricted estimators $\widetilde{\mu}_{i}$. Under $H_{o}$, the restricted maximum of $L_{o}$ is then given by

$$
L_{o}^{*}=-\frac{N}{2} \log (2 \pi)-\sum_{i=1}^{k} n_{i} \log \left(\widetilde{\mu}_{\mathrm{i}} \widetilde{\mathrm{R}}\right)-\frac{\mathrm{N}}{2},
$$

where $N=\sum_{i} n_{i}$. The unrestricted maximum is given by

$$
L^{*}=-\frac{N}{2} \log (2 \pi)-\sum_{i=1}^{k} n_{i} \log \left(S_{n, i}\right)-\frac{N}{2} .
$$

Hence, the traditional likelihood-ratio statistic is given by

$$
\begin{aligned}
-2\left(L_{o}^{*}-L^{*}\right) & =-2\left(-\sum_{i=1}^{k} n_{i} \log \left(\widetilde{\mu}_{i} \widetilde{R}\right)+\sum_{i=1}^{k} n_{i} \log \left(S_{n, i}\right)\right) \\
& =\sum_{i=1}^{k} n_{i} \log \left(\widetilde{\mu}_{i}^{2} \widetilde{R}^{2}\right)-\sum_{i=1}^{k} n_{i} \log \left(S_{n, i}^{2}\right) \\
& =\sum_{i=1}^{k} n_{i} \log \left(\frac{\widetilde{\mu}_{\mathrm{i}}^{2} \widetilde{\mathbf{R}}^{2}}{S_{\mathrm{n}, \mathrm{i}}^{2}}\right) .
\end{aligned}
$$

Under $\mathrm{H}_{0}$, Doornbos and Dijkstra suggest that this statistic is asymptotically distributed as $\chi^{2}$ with ( $\mathrm{k}-1$ ) degrees of freedom. However, an apparent requirement that all $\mathrm{n}_{\mathrm{i}} \rightarrow \infty$ is not stressed (Silvey, 1975, pp. 112-114). This approach illustrates how methods which utilize the normal density are sometimes complicated by the fact that restrictions (and
models) on the CV often cannot be made without addressing additional nuisance parameters.

## Doornbos and Dijkstra's Non-Central t Test

Doornbos and Dijkstra (1983) also suggests an alternative test for the equality of $k$ normal population CVs based on the non-central $t$ distribution (2.1). Let $b_{i}=\frac{1}{r_{i}}, i=1,2$, $\ldots, k$, and define $\bar{b}=\frac{1}{N} \sum_{i=1}^{k} n_{i} b_{i}$, where $N=\sum_{i} n_{i}$. Under $H_{0}: R_{1}=R_{2}=\ldots=R_{k}=R$ (unknown), $\sqrt{\mathrm{n}_{\mathrm{i}}} \mathrm{b}_{\mathrm{i}}$ has a non-central t distribution with $\left(\mathrm{n}_{\mathrm{i}}-1\right)$ degrees of freedom and non-centrality parameter $\frac{\sqrt{n_{i}}}{R}$. It follows that

$$
\begin{align*}
& E\left(b_{i}\right)=\left(\frac{n_{i}-1}{2}\right)^{1 / 2} \frac{\Gamma\left[\frac{1}{2}\left(n_{i}-2\right)\right]}{\Gamma\left[\frac{1}{2}\left(n_{i}-1\right)\right] R}=\frac{\xi_{i}}{R}, \text { and }  \tag{2.6}\\
& E\left(b_{i}^{2}\right)=\frac{n_{i}-1}{n_{i}-3}\left(\frac{1}{n_{i}}+\frac{1}{R^{2}}\right), i=1,2, \ldots, k . \tag{2.7}
\end{align*}
$$

See, for example, Owen (1968). Hence,

$$
\begin{equation*}
E\left(\sum_{i=1}^{k} n_{i} b_{i}^{2}\right)=\sum_{i=1}^{k} \frac{n_{i}-1}{n_{i}-3}+\frac{1}{R^{2}} \sum_{i=1}^{k} \frac{n_{i}\left(n_{i}-1\right)}{n_{i}-3}, \tag{2.8}
\end{equation*}
$$

so that an unbiased estimate of $\frac{1}{\mathrm{R}^{2}}$ is

$$
\begin{equation*}
\widetilde{\mathbf{R}}^{-2}=\frac{\sum_{i=1}^{k} n_{i} b_{i}^{2}-\sum_{i=1}^{k} \frac{n_{i}-1}{n_{i}-3}}{\sum_{i=1}^{k} \frac{n_{i}\left(n_{i}-1\right)}{n_{i}-3}} . \tag{2.9}
\end{equation*}
$$

Define $T=\sum_{i=1}^{k} n_{i}\left(b_{i}-\bar{b}\right)^{2}$. For large $n_{i}$, it follows from the moments of the non-central $t$ given above that $T$ is distributed approximately as $\left(1+\frac{1}{2 \mathbf{R}^{2}}\right) \chi_{k-1}^{2}$ under $H_{0}$. Further,

$$
\begin{aligned}
E(T) & =E\left[\sum_{i=1}^{k} n_{i} b_{i}^{2}-N \bar{b}^{2}\right]=E\left[\sum_{i=1}^{k} n_{i} b_{i}^{2}\right]-\frac{1}{N}\left[E\left(\sum_{i=1}^{k} n_{i} b_{i}\right)^{2}\right] \\
& =E\left[\sum_{i=1}^{k} n_{i} b_{i}^{2}\right]-\frac{1}{N}\left[\operatorname{Var}\left(\sum_{i=1}^{k} n_{i} b_{i}\right)+\left(E\left(\sum_{i=1}^{k} n_{i} \mathbf{b}_{i}\right)\right)^{2}\right] \\
& =E\left[\sum_{i=1}^{k} n_{i} b_{i}^{2}\right]-\frac{1}{N}\left[\sum_{i=1}^{k} n_{i}^{2} \operatorname{Var}\left(b_{i}\right)+\left(E\left(\sum_{i=1}^{k} n_{i} b_{i}\right)\right)^{2}\right] \\
& =E\left[\sum_{i=1}^{k} n_{i} b_{i}^{2}\right]-\frac{1}{N}\left[\sum_{i=1}^{k} n_{i}^{2}\left[E\left(b_{i}^{2}\right)-\left(E\left(b_{i}\right)\right)^{2}\right]+\left(\sum_{i=1}^{k} n_{i} E\left(b_{i}\right)\right)^{2}\right] .
\end{aligned}
$$

Substituting (2.6), (2.7), and (2.8) into this last equation gives

$$
\begin{aligned}
E(T)=\sum_{i=1}^{k} & \frac{\left(N-n_{i}\right)\left(n_{i}-1\right)}{N\left(n_{i}-3\right)} \\
& +\frac{1}{R^{2}}\left\{\sum_{i=1}^{k} \frac{n_{i}\left(N-n_{i}\right)\left(n_{i}-1\right)}{N\left(n_{i}-3\right)}+\frac{1}{N}\left[\sum_{i=1}^{k} n_{i}^{2} \xi_{i}^{2}-\left(\sum_{i=1}^{k} n_{i} \xi_{i}\right)^{2}\right]\right] .
\end{aligned}
$$

Finally, substituting (2.9) for $\frac{1}{\mathrm{R}^{2}}$ and denoting the result by $\overline{\mathrm{E}(\mathrm{T})}$, it follows that for
large samples $\overline{\mathrm{E}(\mathrm{T})} \approx \mathrm{E}(\mathrm{T}) \approx\left(1+\frac{1}{2 \mathrm{R}^{2}}\right)(\mathrm{k}-1)$, so that under $\mathrm{H}_{\mathrm{o}},(\mathrm{k}-1) \frac{\mathrm{T}}{\overline{\mathrm{E}(\mathrm{T})}}$ has approximately a $\chi^{2}$ distribution with $(k-1)$ degrees of freedom.

## Gupta and Ma's Wald Test

Gupta and Ma (1996) proposes a Wald procedure for testing $\mathbf{H}_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots$ $=R_{k}$ based on an earlier form by Rao and Vidya (1992), which deals only with two populations and equal sample sizes. Gupta and Ma suggest the following general theory: Under regularity conditions satisfied by the normal log-likelihood, suppose that a random sample of size n is taken from a distribution with parameter vector $\theta=\left(\theta_{1}, \theta_{2}, \ldots, \theta_{\mathrm{p}}\right)^{\prime}$. Let $\hat{\theta}=\left(\hat{\theta}_{1}, \hat{\theta}_{2}, \ldots, \hat{\theta}_{\mathrm{p}}\right)^{\prime}$ be the unrestricted maximum-likelihood estimate of $\theta$ obtained via the $\log$-likelihood $L(\theta)$. Then a test for $H_{0}: \mathbf{k}(\theta)=\left(\left(k_{1}(\theta), k_{2}(\theta), \ldots, \mathrm{k}_{\mathrm{m}}(\theta)\right)^{\prime}=\mathbf{0}\right.$, where the $\mathrm{k}_{\mathrm{i}}$ are differentiable with respect to $\theta$, is given via the statistic

$$
\begin{equation*}
\mathbf{k}^{\prime}(\hat{\boldsymbol{\theta}})\left[\hat{\mathbf{K}}^{\prime}(\mathbf{I} \hat{\mathbf{n}})^{-1} \hat{\mathbf{K}}\right]^{-1} \mathbf{k}(\hat{\boldsymbol{\theta}}) \tag{2.10}
\end{equation*}
$$

where $\hat{\mathbf{K}}$ is a $\mathrm{p} \times \mathrm{m}$ matrix having entries $\mathrm{k}_{\mathrm{ij}}=\partial \mathrm{k}_{\mathrm{j}}(\boldsymbol{\theta}) / \partial \theta_{\mathrm{i}}, \mathrm{i}=1,2, \ldots, \mathrm{p}, \mathrm{j}=1,2, \ldots, \mathrm{~m}$ estimated at $\hat{\boldsymbol{\theta}}$ and where Inf is the $\mathrm{p} \times \mathrm{p}$ Fisher's information matrix having entries $\mathrm{i}_{\mathrm{jk}}=-\mathrm{E}\left(\frac{\partial^{2} \mathrm{~L}(\theta)}{\partial \theta_{\mathrm{j}} \partial \theta_{\mathrm{k}}}\right), \mathrm{j}, \mathrm{k}=1,2, \ldots, \mathrm{p}$, also evaluated at $\hat{\boldsymbol{\theta}}$. Under $\mathrm{H}_{\mathrm{o}},(2.10)$ has a $\chi^{2}$ distribution with m degrees of freedom for large n (Silvey, 1975, pp. 115-116).

$$
\text { Gupta and Ma take } \theta=\left(\mu_{1}, \sigma_{1}, \mu_{2}, \sigma_{2}, \ldots, \mu_{\mathrm{k}}, \sigma_{\mathrm{k}}\right)^{\prime} \text { and } \mathrm{k}_{\mathrm{i}}(\theta)=\frac{\sigma_{\mathrm{i}}}{\mu_{\mathrm{i}}}-\frac{\sigma_{\mathrm{i}+1}}{\mu_{\mathrm{i}+1}}, \mathrm{i}=1,
$$

$2, \ldots, k-1$ to test $H_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{\mathrm{k}}$, where $\mathrm{L}(\theta)=-\sum_{\mathrm{i}=1}^{\mathrm{k}} \mathbf{n}_{\mathrm{i}} \log \left((2 \pi)^{1 / 2} \sigma_{\mathrm{i}}\right)-$ $\sum_{i=1}^{k} \sum_{j=1}^{n_{i}} \frac{\left(X_{i j}-\mu_{i}\right)^{2}}{2 \sigma_{i}^{2}}$. From (2.10), for $k=2$, they obtain

$$
\begin{equation*}
\frac{\left(\mathrm{r}_{\mathrm{n}, 1}-\mathrm{r}_{\mathrm{n}, 2}\right)^{2}}{\frac{\mathrm{r}_{\mathrm{n}, 1}^{2}}{2 \mathrm{n}_{1}}+\frac{\mathrm{r}_{\mathrm{n}, 1}^{4}}{\mathrm{n}_{1}}+\frac{\mathrm{r}_{\mathrm{n}, 2}^{2}}{2 \mathrm{n}_{2}}+\frac{\mathrm{r}_{\mathrm{n}, 2}^{4}}{\mathrm{n}_{2}}}, \tag{2.11}
\end{equation*}
$$

while for $k=3$, (2.10) gives

$$
\binom{r_{n, 1}-r_{n, 2}}{r_{n, 2}-r_{n, 3}}^{\prime}\left(\begin{array}{ccc}
\frac{r_{n, 1}^{2}}{2 n_{1}}+\frac{r_{n, 1}^{4}}{n_{1}}+\frac{r_{n, 2}^{2}}{2 n_{2}}+\frac{r_{n, 2}^{4}}{n_{2}} & -\frac{r_{n, 2}^{2}}{2 n_{2}}-\frac{r_{n, 2}^{4}}{n_{2}}  \tag{2.12}\\
-\frac{r_{n, 2}^{2}}{2 n_{2}}-\frac{r_{n, 2}^{4}}{n_{2}} & \frac{r_{n, 2}^{2}}{2 n_{2}}+\frac{r_{n, 2}^{4}}{n_{2}}+\frac{r_{n, 3}^{2}}{2 n_{3}}+\frac{r_{n, 3}^{4}}{n_{3}}
\end{array}\right)^{-1}\binom{r_{n, 1}-r_{n, 2}}{r_{n, 2}-r_{n, 3}} .
$$

They state that for $k>3$, the general formula is omitted "because of its complexity". In order for this application of Wald theory to apply, however, it is apparently necessary that all $n_{i} \rightarrow \infty$ (Silvey, 1975, pp. 115-118), a requirement which Gupta and Ma do not address.

Gupta and Ma also do not simplify their statistics. For example, (2.11) may be reexpressed as

$$
\frac{\left(\mathrm{r}_{\mathrm{n}, 1}-\mathrm{r}_{\mathrm{n}, 2}\right)^{2}}{\frac{\mathrm{r}_{\mathrm{n}, 1}^{2}}{\mathrm{n}_{1}}\left(\mathrm{r}_{\mathrm{n}, 1}^{2}+\frac{1}{2}\right)+\frac{\mathrm{r}_{\mathrm{n}, 2}^{2}}{\mathrm{n}_{2}}\left(\mathrm{r}_{\mathrm{n}, 2}^{2}+\frac{1}{2}\right)}=(\mathbf{C r})^{\prime}\left[\mathbf{C} \hat{\mathbf{V}} \mathbf{C}^{\prime}\right]^{-1}(\mathbf{C r})
$$

where $\mathbf{C}=(1,-1), \mathbf{r}=\left(r_{n, 1}, r_{n, 2}\right)^{\prime}$, and $\hat{\mathbf{V}}=\operatorname{diag}\left\{\frac{r_{n, i}^{2}}{n_{i}}\left(r_{n, i}^{2}+\frac{1}{2}\right)\right\}, i=1$, 2. Similarly, (2.12) may be simplified in this way by taking $\mathbf{C}=\left[\begin{array}{ccc}1 & -1 & 0 \\ 0 & 1 & -1\end{array}\right]$ and expanding $\mathbf{r}$ and $\hat{\mathbf{V}}$ to contain a third element. These simplifications suggest that Gupta and Ma's test may also be obtained from the discussion surrounding the Iglewicz and Myers' approximation by noting that since the samples are independent, $\mathbf{r}=\left(\mathrm{r}_{\mathrm{n}, 1}, \mathrm{r}_{\mathrm{n}, 2}, \ldots \mathrm{r}_{\mathrm{n}, \mathrm{k}}\right)^{\prime}$ is asymptotically normal with mean $\mathbf{R}=\left(\mathbf{R}_{1}, \mathbf{R}_{2}, \ldots \mathbf{R}_{\mathrm{k}}\right)^{\prime}$ and covariance matrix $\mathbf{V}=\operatorname{diag}\left\{\frac{\mathbf{R}_{\mathrm{i}}^{2}}{\mathbf{n}_{\mathrm{i}}}\left(\mathbf{R}_{\mathrm{i}}^{2}+\frac{1}{2}\right)\right\}$. Hence, under $H_{0}: \mathbf{C R}=\mathbf{0}$, where $\mathbf{C}=\left[\begin{array}{ccccccc}1 & -1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 1 & -1 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 1 & -1\end{array}\right]$ is a $(\mathrm{k}-1) \mathrm{x} k$ matrix of restrictions on $\mathbf{R}$ corresponding to $\mathbf{R}_{\mathbf{1}}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{k}, \mathbf{C r}$ is asymptotically normal with mean 0 and covariance matrix $\mathbf{C V C}^{\prime}$. Evaluating $\mathbf{V}$ at $\mathbf{r}$ to obtain $\hat{\mathbf{V}}$, it follows that $(\mathbf{C r})^{\prime}\left[\mathbf{C} \hat{\mathbf{V}} \mathbf{C}^{\prime}\right]^{-1}(\mathbf{C r})$ is asymptotically distributed as $\chi^{2}$ with $(\mathrm{k}-1)$ degrees of freedom under $\mathrm{H}_{\mathrm{o}}$ for large $\mathrm{n}_{\mathrm{i}}$ (Serfling, 1980, pp. 128-130, 155; Judge, et al., 1988, pp. 52, 109110; Eliason, 1993, pp. 34-35).

## Gupta and Ma's Score Test

Gupta and Ma (1996) also develops a likelihood-based test that utilizes a reparameterized normal density and the following general theory: Under regularity conditions satisfied by the normal log-likelihood, suppose that a random sample of size $n$
is taken from a distribution with parameter vector $\theta=\left(\theta_{1}, \theta_{2}, \ldots, \theta_{\mathrm{p}}\right)^{\prime}$. Assume $\widetilde{\theta}=\left(\widetilde{\theta}_{1}, \widetilde{\theta}_{2}, \ldots, \widetilde{\theta}_{\mathrm{p}}\right)^{\prime}$ is the restricted maximum-likelihood estimate of $\theta$ obtained via the $\log$-likelihood $L(\theta)$ under $H_{0}: \mathbf{k}(\theta)=\left(\left(k_{1}(\theta), k_{2}(\theta), \ldots, k_{m}(\theta)\right)^{\prime}=\mathbf{0}\right.$. Let $\mathbf{U}(\theta)$ be ap x 1 vector having elements $u_{i}=\partial L(\theta) / \partial \theta_{i}, i=1,2, \ldots, p$. Then a test of $H_{o}$ is given via the statistic

$$
\begin{equation*}
(\mathbf{U}(\widetilde{\boldsymbol{\theta}}))^{\prime}(\mathbf{I} \widetilde{\mathbf{n}} \mathbf{f})^{-1}(\mathbf{U}(\widetilde{\theta})) \tag{2.13}
\end{equation*}
$$

where Inf is the $p \times p$ Fisher's information matrix having entries $i_{j k}=-E\left(\frac{\partial^{2} L(\theta)}{\partial \theta_{j} \partial \theta_{k}}\right), j, k$ $=1,2, \ldots, p$, evaluated at $\widetilde{\theta}$. Under $H_{o},(2.13)$ has a $\chi^{2}$ distribution with $m$ degrees of freedom for large n (Rao, 1973, pp. 418-420; Silvey, 1975, pp. 118-120).

$$
\text { Gupta and Ma take } \theta=\left(\mathbf{R}_{1}, \mathbf{R}_{2}, \ldots, \mathbf{R}_{k}, \mu_{1}, \mu_{2}, \ldots, \mu_{\mathrm{k}}\right)^{\prime} \text { and } \mathrm{k}_{\mathrm{i}}(\theta)=\mathbf{R}_{\mathrm{i}}-\mathbf{R}_{\mathrm{i}+1}, \mathbf{i}=
$$

$1,2, \ldots, k-1$ to test $H_{0}: R_{1}=R_{2}=\ldots=R_{k}=R$ (unknown), where the reparameterized
normal likelihood $L(\theta)=-\sum_{i=1}^{k} n_{i} \log \left((2 \pi)^{1 / 2} \mu_{i} R_{i}\right)-\sum_{i=1}^{k} \sum_{j=1}^{n_{i}} \frac{\left(X_{i j}-\mu_{i}\right)^{2}}{2 \mu_{i}^{2} R_{i}^{2}}$. From (2.13),
they obtain

$$
\widetilde{\mathbf{R}}^{2}\left(\widetilde{\mathbf{R}}^{2}+\frac{1}{2}\right) \sum_{\mathrm{i}=1}^{\mathrm{k}} \frac{\mathrm{a}_{\mathrm{i}}^{2}}{\mathbf{n}_{\mathrm{i}}}
$$

where $\mathbf{a}_{\mathrm{i}}=\frac{\sum_{\mathrm{j}=\mathbf{1}}^{\mathbf{n}_{i}}\left(\mathbf{X}_{\mathrm{ij}}-\widetilde{\mu}_{\mathrm{i}}\right)^{2}}{\widetilde{\mu}_{\mathrm{i}}^{2} \widetilde{\mathbf{R}}^{3}}-\frac{\mathbf{n}_{i}}{\widetilde{\mathbf{R}}}, \mathbf{i}=1,2, \ldots, k$, and where $\widetilde{\mathbf{R}}$ and $\widetilde{\mu}_{i}$ are the restricted parameter estimates under $H_{0}$, obtained via the iterative algorithm outlined above for

Doornbos and Dijkstra's likelihood-ratio test. Once again, however, an apparent requirement that all $\mathbf{n}_{\mathrm{i}} \rightarrow \infty$ is not addressed.

## Feltz and Miller's Test

Feltz and Miller (1996) suggests a test for the equality of $k$ normal population CVs which is developed solely from the standpoint of asymptotic moments, much like the simplification of the Wald test offered above. Feltz and Miller note that since the samples are independent, $\mathbf{r}=\left(\mathrm{r}_{1}, \mathrm{r}_{2}, \ldots \mathrm{r}_{\mathrm{k}}\right)^{\prime}$ is asymptotically normal with mean $\mathbf{R}=\left(\mathbf{R}_{1}, \mathbf{R}_{2}, \ldots \mathbf{R}_{k}\right)^{\prime}$ and covariance matrix $\mathbf{V}=\operatorname{diag}\left\{\frac{\mathbf{R}_{i}^{2}}{\mathbf{n}_{i}}\left(\mathbf{R}_{i}^{2}+\frac{1}{2}\right)\right\}, i=1,2, \ldots, k$. Under $H_{0}: \mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{\mathrm{k}}=\mathbf{R}$ (unknown), $\mathbf{V}$ simplifies to $\mathbf{R}^{2}\left(\mathbf{R}^{2}+\frac{1}{2}\right) \operatorname{diag}\left\{\mathrm{n}_{\mathrm{i}}^{-1}\right\}$. Constructing the quadratic form $\mathbf{r}^{\prime} A \mathbf{r}$ under $\mathrm{H}_{\mathrm{o}}$, with $\mathbf{A}=\mathbf{V}^{-1}-\left(\mathbf{V}^{-1} \mathbf{J} \mathbf{V}^{-1}\right) /\left(\mathbf{1}^{\prime} \mathbf{V}^{-1} \mathbf{1}\right)$, where $\mathbf{J}$ is a $\mathbf{k} \mathbf{x k}$ matrix of ones and $\mathbf{1}$ is akx 1 vector of ones, Feltz and Miller note that since $\mathbf{A V}$ is idempotent, then $\mathbf{r}^{\prime} \mathbf{A r}$ is asymptotically distributed as $\chi^{2}$ with ( $k-1$ ) degrees of freedom (for large $n_{i}$ ) (Serfling, 1980, pp. 128-129). Simplified and evaluated at $\mathbf{r}$,

$$
\mathbf{r}^{\prime} \mathbf{A r}=\left[\widetilde{\mathbf{R}}^{2}\left(\widetilde{\mathbf{R}}^{2}+\frac{1}{2}\right)\right]^{-1}\left(\sum_{\mathrm{i}=1}^{\mathrm{k}} \mathbf{n}_{\mathrm{i}}\left(\mathrm{r}_{\mathrm{i}}-\widetilde{\mathbf{R}}\right)^{2}\right),
$$

where, for $N=\sum_{i} n_{i}, \widetilde{R}=\left(\sum_{i=1}^{k} n_{i} r_{i}\right) / N$ is offered as a reasonable estimate of $R$ under
$H_{0}$. Note that $\widetilde{R}$ is simply the weighted average of the $r_{i}$.

## Factorial Designs for Population CVs

## The Taguchi Approach

The methods of statistical experimental design have taken an increasingly important role in industry worldwide, as businesses seek to improve product quality and consistency, while minimizing cost. At the core of this movement have been the Taguchi methods, which utilize some of the more basic concepts of experimental design to great effect.

Among the responses of interest are the Taguchi signal-to-noise ratios, which are calculated within treatment combinations and are designed to reflect the effect of the individual treatments on the ability of a process to attain a designated target value. In particular, if it is desired to identify treatment factors that are important for maintaining closeness to a finite, positive average with minimum variation, Taguchi (1992, pp. 120124) suggests that the response statistic $10 \log _{10}\left(\frac{1}{r_{i}^{2}}-\frac{1}{n_{i}}\right)$ be analyzed in the context of a fractional factorial design. Noting that for values of $r_{i} \leq 0.3$ and $n_{i} \geq 2$, the term $1 / n_{i}$ is proportionately small, an alternative ratio is often given as $10 \log _{10}\left(\frac{1}{r_{i}^{2}}\right)=-20 \log _{10} r_{i}$ (Maghsoodloo, 1990; Schmidt and Launsby, 1994, Ch. 5, p. 18), which is simply the logtransformed sample CV.

Under a null hypothesis of no factor effects, these statistics have constant variance. A typical approach, then, is to conduct a standard normal-theory analysis of variance, treating the signal-to-noise ratios as the responses. However, there is only a single
statistic per treatment combination, so that no estimate of the experimental error is available unless at least one mean square (corresponding to the highest-order interaction in a full factorial, presumably) is used for this purpose. Unfortunately, in the context of fractional factorials, there is usually no clearly defined hierarchy of effects, so that the one or several very small effects are pooled to create an estimate of the error. This process tends to produce tests of factor effects that have inflated Type I error rates because of the post-test selection of small effects (Box, 1988; Bissell, 1989; Zacks, 1991). In addition, at least one factor must always be declared negligible, even though experimental results may suggest that all factors are potentially important.

## Bissell's Approach

Bissell (1989) proposes two procedures that simultaneously solve the bias problem and the lack of a test for all factor effects while maintaining a normal-theory analysis of variance of the signal-to-noise ratios.

According to his first solution, suppose there are a total of $k$ factors, arranged in his example according to a fractional factorial. Calculate the mean squares $\mathbf{M}_{1}, \mathbf{M}_{2}, \ldots, \mathbf{M}_{\mathrm{k}}$ of the response signal-to-noise ratios and compute the overall average mean square $\overline{\mathbf{M}}=\sum_{i=1}^{k} \mathbf{M}_{i} / k$. If each factor has, say, $\kappa$ degrees of freedom, then under the assumption of homogeneity of mean squares (that is, no factor effects), the common variance of the $\mathrm{M}_{\mathrm{i}}$ may be estimated as $2 \overline{\mathrm{M}}^{2} / \mathrm{K}$. A statistic for testing the deviation of at least one $\mathrm{M}_{\mathrm{i}}$ from this hypothesis is then

$$
\frac{(\mathrm{k}-1) \operatorname{Var}\left(\mathbf{M}_{\mathrm{i}}\right)}{2 \overline{\mathrm{M}}^{2} / \kappa}=\frac{(\mathrm{k}-1) \kappa \operatorname{Var}\left(\mathbf{M}_{\mathrm{i}}\right)}{2 \overline{\mathrm{M}}^{2}}
$$

where $\operatorname{Var}\left(\mathbf{M}_{\mathbf{i}}\right)=\sum_{\mathrm{i}=1}^{\mathrm{k}}\left(\mathbf{M}_{\mathbf{i}}-\overline{\mathbf{M}}\right)^{2} /(\mathrm{k}-1)$ is the observed variance of the $\mathbf{M}_{\mathrm{i}}$. Under the null hypothesis of homogeneity, this statistic has an approximate $\chi^{2}$ distribution with $(k-1)$ degrees of freedom. If the hypothesis of homogeneity is rejected, Bissell suggests identifying the largest mean square as corresponding to a significant effect, removing it from consideration, and repeating the entire process until the hypothesis of homogeneity is not rejected.

Bissell's application of this procedure is to fractional factorials, which typically do not have hierarchy restrictions on factors since interactions are often not considered.

However, it also could be used in more traditional full factorial settings by examining specific terms in order.

Bissell's second solution also addresses the problem from a homogeneity standpoint using the well-known Bartlett's test for equality of variances. Assuming that each of the k factors has k degrees of freedom, Bissell's variant, applied to the mean squares, is

$$
\mathbf{B}=\log \left(\frac{1}{\mathrm{k}} \sum_{\mathrm{i}=1}^{\mathrm{k}} \mathrm{M}_{\mathrm{i}}\right)-\frac{1}{\mathrm{k}} \sum_{\mathrm{i}=1}^{\mathrm{k}} \log \left(\mathrm{M}_{\mathrm{i}}\right)
$$

where Box's small-sample correction gives that $\left(\mathrm{kkf}_{2} \mathrm{~B}\right) /\left(\mathrm{f}_{1}(\mathrm{~b}-\mathrm{kk} \mathrm{B})\right)$ has approximately an $F$ distribution with $f_{1}$ and $f_{2}$ degrees of freedom under the null hypothesis of homogeneity of mean squares, with $f_{1}=k-1$ and $f_{2}=(k-1) / A^{2}$, where $A=$ $1+(k+1) /(2 k k)$, and where $b=f_{2} /\left(1-A+2 / f_{2}\right)$. Bissell utilizes a top-down
approach for the elimination of factors as in his first solution, wherein the effects are removed in descending order according to size until the null hypothesis of homogeneity is not rejected. He notes general agreement between his two procedures, although a power analysis was not conducted.

## Zacks' Approach

An alternative correction for the bias induced by selecting the several smallest effects post-test is discussed by Zacks (1991), who considers modified F critical values. However, this approach does not address the lack of a test of all factor effects. An additional apparent shortcoming of Zacks' approach and of the related approaches discussed above is that subsequent analysis of the CV itself is somewhat compromised by the log transformation and the corresponding assumption of equal variance, which is incorrect outside the null hypothesis of no factor effects.

## CHAPTER THREE

## REVIEW OF THEORY

In this chapter, the theories of maximum- and quasi-likelihood estimation and their application in the context of the generalized linear model are discussed. In Chapter Four, these techniques will be applied to the approximate distributions of the sample CV discussed in Chapter Two in order to estimate the parameters of a factorial model of the population CV, once a proper form for such a model is proposed.

The Exponential Family

Let Y be a random variable whose probability function may be expressed in the form

$$
\begin{equation*}
f(y ; \theta, \phi)=\exp \{(y \theta-b(\theta)) / a(\phi)+c(y, a(\phi))\} \tag{3.1}
\end{equation*}
$$

with parameters $\theta$ and $\phi$ for suitably chosen functions $\mathrm{a}(\bullet), \mathrm{b}(\bullet)$, and $\mathrm{c}(\bullet)$. The parameter $\theta$ is called the natural parameter and $\phi$ is called the dispersion parameter. If $\phi$ is known, such a function is said to belong to the exponential family. Examples include the binomial and Poisson. For unknown $\phi$, (3.1) encompasses the two-parameter exponential family, which includes the gamma and the normal.

McCullagh and Nelder (1989, pp. 28-29), and Agresti (1990, p. 446-447)
demonstrate how the first two moments of $Y$ can be expressed in terms of $\theta$ and $\phi$. Let
$\ell(\theta, \phi ; \mathbf{y})=\log \mathrm{f}(\mathrm{y} ; \theta, \phi)$ be the $\log$-likelihood of Y . Then

$$
\ell(\theta, \phi ; \mathrm{y})=(\mathrm{y} \theta-\mathrm{b}(\theta)) / \mathrm{a}(\phi)+\mathrm{c}(\mathrm{y}, \mathrm{a}(\phi))
$$

and so

$$
\frac{\partial \ell}{\partial \theta}=\frac{\left(\mathrm{y}-\mathrm{b}^{\prime}(\theta)\right)}{\mathrm{a}(\phi)}, \quad \quad \frac{\partial^{2} \ell}{\partial \theta^{2}}=-\frac{\mathrm{b}^{\prime \prime}(\theta)}{\mathrm{a}(\phi)} .
$$

Under regularity conditions satisfied by (3.1), it follows that $E\left(\frac{\partial \ell}{\partial \theta}\right)=0$ and $E\left(\frac{\partial^{2} \ell}{\partial \theta^{2}}\right)+$
$\mathrm{E}\left(\frac{\partial \ell}{\partial \theta}\right)^{2}=0$. Hence,

$$
\mathrm{E}\left(\frac{\mathrm{Y}-\mathrm{b}^{\prime}(\theta)}{\mathrm{a}(\phi)}\right)=\frac{\mathrm{E}(\mathrm{Y})-\mathrm{b}^{\prime}(\theta)}{\mathrm{a}(\phi)}=0
$$

which implies that $\mathrm{E}(\mathrm{Y})=\psi=\mathbf{b}^{\prime}(\theta)$. Similarly,

$$
E\left(-\frac{b^{\prime \prime}(\theta)}{a(\phi)}\right)+E\left(\frac{Y-b^{\prime}(\theta)}{a(\phi)}\right)^{2}=-\frac{b^{\prime \prime}(\theta)}{a(\phi)}+\frac{\operatorname{Var}(Y)}{[a(\phi)]^{2}}=0
$$

which implies that $\operatorname{Var}(Y)=a(\phi) b^{\prime \prime}(\theta)$. The function $b^{\prime \prime}(\theta)$ depends only on the mean $\psi$ via the natural parameter $\theta$ and is called the variance function. The notation $\mathrm{V}(\psi)$ is typically used. The function $a(\phi)$ typically has the form $a(\phi)=\phi / w$, where $w$ is a known weight. In the future, the weight $w$ will be absorbed into $\mathrm{V}(\psi)$, so that the notation $\operatorname{Var}(\mathrm{Y})=\phi \mathrm{V}(\psi)$ will be employed. Additionally, noting that $\frac{\partial \psi}{\partial \theta}=\mathrm{b}^{\prime \prime}(\theta)=\frac{\operatorname{Var}(\mathrm{Y})}{\mathrm{a}(\phi)}$, it
follows that

$$
\begin{equation*}
\frac{\partial \ell}{\partial \psi}=\frac{\partial \ell}{\partial \theta} \frac{\partial \theta}{\partial \psi}=\frac{\mathrm{y}-\psi}{\mathrm{a}(\phi)} \frac{\mathrm{a}(\phi)}{\operatorname{Var}(\mathrm{Y})}=\frac{\mathrm{y}-\psi}{\operatorname{Var}(\mathrm{Y})} \tag{3.2}
\end{equation*}
$$

Wedderburn (1974) shows that (3.2) is, in fact, a property possessed solely by probability functions of the form (3.1).

## Maximum-Likelihood Estimation

Let $\mathbf{Y}=\left(\mathbf{Y}_{1}, \mathbf{Y}_{2}, \ldots, \mathbf{Y}_{\mathrm{N}}\right)^{\prime}$ be a vector of independent observations with expectation $\psi=\left(\psi_{1}, \psi_{2}, \ldots, \psi_{\mathrm{N}}\right)^{\prime}$ and covariance matrix $\phi \mathbf{V}(\psi)=\phi \operatorname{diag}\left\{\mathrm{V}_{1}\left(\psi_{1}\right), \mathrm{V}_{2}\left(\psi_{2}\right)\right.$, $\left.\ldots, \mathrm{V}_{\mathrm{N}}\left(\psi_{\mathrm{N}}\right)\right\}$, and let the probability function of the $\mathrm{Y}_{\mathrm{i}}, \mathrm{i}=1,2, \ldots, \mathrm{~N}$, have the form (3.1). Using conditions established by McCullagh $(1983,1986)$, suppose that $\psi$ is related to a pdimensional parameter vector $\beta=\left(\beta_{1}, \beta_{2}, \ldots, \beta_{p}\right)^{\prime}$ through an arbitrary (possibly nonlinear) regression model $\psi=\psi(\beta)$ such that $\partial^{3} \psi_{i}(\beta) / \partial \beta_{j}^{3}$ are bounded for $i=1,2$, $\ldots, \mathrm{N}, \mathrm{j}=1,2, \ldots, \mathrm{p}$, and such that if $\boldsymbol{\beta} \neq \boldsymbol{\beta}^{\prime}$ then $\psi(\boldsymbol{\beta}) \neq \psi\left(\boldsymbol{\beta}^{\prime}\right)$ (that is, assume that the model is identifiable). Let $\ell_{\mathrm{i}}$ denote the log-likelihood of the $\mathrm{i}^{\text {th }}$ observation. Then the $\log$-likelihood of the N observations as a function of $\boldsymbol{\beta}$ via $\psi(\beta)$ is $L(\beta)=\sum_{i=1}^{N} \ell_{i}$. A commonly used iterative method for determining the vector $\hat{\beta}$ that maximizes $L(\beta)$, that is, determines the solution of $\partial \mathrm{L}(\beta) / \partial \beta=0$, is a variation of the Newton-Raphson algorithm known as Fisher scoring, discussed in Judge, et al. (1988, pp. 524-527), Agresti (1990, pp. 447-451) and Eliason (1993, pp. 41-45).

## The Newton-Raphson Algorithm

Given a suitable initial estimate $\beta^{(0)}$ of $\beta$, let $\beta^{(t)}$ denote the approximation of $\beta$ at the $t^{\text {th }}$ iteration. Then the $(t+1)^{\text {th }}$ estimate of $\beta$ is given via the Newton-Raphson algorithm as

$$
\begin{equation*}
\boldsymbol{\beta}^{(t+1)}=\boldsymbol{\beta}^{(t)}-\left(\mathbf{H}^{(t)}\right)^{-1} \mathbf{q}^{(t)} \tag{3.3}
\end{equation*}
$$

where $q^{(t)}$ is the vector of estimating equations $\partial L(\beta) / \partial \beta$ having elements

$$
\frac{\partial L(\beta)}{\partial \beta_{j}}=\sum_{i=1}^{N} \frac{\partial \ell_{i}}{\partial \beta_{j}}
$$

with

$$
\frac{\partial \ell_{i}}{\partial \beta_{j}}=\frac{\partial \ell_{i}}{\partial \psi_{i}} \frac{\partial \psi_{i}}{\partial \beta_{j}}=\frac{y_{i}-\psi_{i}}{\phi V_{i}\left(\psi_{i}\right)} \frac{\partial \psi_{i}}{\partial \beta_{j}}
$$

evaluated at $\boldsymbol{\beta}^{(t)}$, and where $\mathbf{H}^{(t)}$ is the Hessian matrix (assumed nonsingular) having elements $\mathrm{h}_{\mathrm{kj}}=\partial^{2} \mathrm{~L}(\beta) / \partial \beta_{\mathrm{k}} \partial \beta_{\mathrm{j}}$, with

$$
\begin{align*}
\frac{\partial^{2} L(\beta)}{\partial \beta_{k} \partial \beta_{j}} & =\frac{\partial}{\partial \beta_{k}}\left(\sum_{i=1}^{N} \frac{y_{i}-\psi_{i}}{\phi V_{i}\left(\psi_{i}\right)} \frac{\partial \psi_{i}}{\partial \beta_{j}}\right) \\
& =\frac{1}{\phi} \sum_{i=1}^{N}\left(\left(y_{i}-\psi_{i}\right) \frac{\partial}{\partial \beta_{k}}\left[\frac{1}{V_{i}\left(\psi_{i}\right)} \frac{\partial \psi_{i}}{\partial \beta_{j}}\right]-\left[\frac{1}{V_{i}\left(\psi_{i}\right)} \frac{\partial \psi_{i}}{\partial \beta_{j}} \frac{\partial \psi_{i}}{\partial \beta_{k}}\right]\right), \tag{3.4}
\end{align*}
$$

also evaluated at $\beta^{(t)}$. In vector form, the estimating equations may be written as

$$
\mathrm{U}(\boldsymbol{\beta})=\frac{\partial \mathrm{L}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}}=\mathbf{D}^{\prime} \mathbf{V}^{-1}(\mathbf{y}-\psi(\boldsymbol{\beta})) / \phi
$$

where $\mathbf{D}$ has elements $\mathfrak{d}_{\mathrm{ij}}=\partial \psi_{\mathrm{i}} / \partial \boldsymbol{\beta}_{\mathrm{j}}$ and $\mathbf{y}=\left(\mathrm{y}_{1}, \mathbf{y}_{2}, \ldots, \mathbf{y}_{\mathrm{N}}\right)^{\prime}$, and where, under the identifiability condition on the model, $D$ has full rank. The vector $U(\beta)$ is commonly called the score vector. Note that the (possibly) unknown dispersion parameter $\phi$ cancels in the iterative equation (3.3) and does not affect the estimation of $\beta$.

## The Fisher Scoring Algorithm

Fisher scoring replaces $-\mathbf{H}$ with its expectation, also known as the Fisher's information matrix. In this case $\operatorname{Inf}=-\mathrm{E}(\mathbf{H})$ has elements

$$
\mathrm{i}_{\mathrm{kj}}=\frac{1}{\phi} \sum_{\mathrm{i}=1}^{\mathrm{N}} \frac{1}{\mathrm{~V}_{\mathrm{i}}\left(\psi_{\mathrm{i}}\right)} \frac{\partial \psi_{\mathrm{i}}}{\partial \beta_{\mathrm{j}}} \frac{\partial \psi_{\mathrm{i}}}{\partial \beta_{\mathrm{k}}}
$$

a fact obtained from (3.4) by noting that the first term of the summand has expectation zero. Hence, at the $t^{\text {th }}$ iteration, $\operatorname{Inf}{ }^{(t)}$, not $\mathbf{H}^{(t)}$, is evaluated at $\beta^{(t)}$. In matrix form, $\operatorname{Inf}=$ $\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D} / \phi$. Substitution into the Newton-Raphson algorithm gives two forms of the iterative equations:

$$
\begin{align*}
\beta^{(t+1)} & =\boldsymbol{\beta}^{(t)}+\left(\mathbf{I n f}^{(t)}\right)^{-1} \mathbf{q}^{(t)}  \tag{3.5}\\
& =\boldsymbol{\beta}^{(t)}+\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1} \mathbf{D}^{\prime} \mathbf{V}^{-1}\left(\mathbf{y}-\psi\left(\boldsymbol{\beta}^{(t)}\right)\right) \tag{3.6}
\end{align*}
$$

where, as before, both $\mathbf{D}$ and $\mathbf{V}$ are evaluated at $\boldsymbol{\beta}^{(t)}$. For both the Newton-Raphson and Fisher scoring methods, iteration continues until changes in $\beta^{(t)}$ are acceptably small.

## Alternate Step Lengths

In order to reduce the possibility that the iterative equations (3.3) or (3.5) will overstep the maximum of the likelihood surface and fail to converge, the Newton-Raphson
and Fisher scoring algorithms are often modified to include a step length (Judge, et al., 1988, pp. 517, 524; Eliason, 1993, p. 45). In particular, the Newton-Raphson algorithm may be rewritten as

$$
\beta^{(t+1)}=\beta^{(t)}-s_{t}\left(\mathbf{H}^{(t)}\right)^{-1} \mathbf{q}^{(t)}
$$

where $s_{t}$ is a constant which may be adjusted at each iteration. The Fisher scoring algorithm is modified according to

$$
\boldsymbol{\beta}^{(t+1)}=\boldsymbol{\beta}^{(t)}+\mathbf{s}_{\mathrm{t}}\left(\operatorname{Inf}^{(t)}\right)^{-1} \mathbf{q}^{(t)}
$$

If $s_{t}=1$ for all $t$, these algorithms reduce to the forms (3.3) and (3.5) given above.
Some techniques call for $\mathrm{s}_{\mathrm{t}}$ to be adjusted at each iteration in order to achieve the optimum movement toward the maximum. However, for simplicity, a fixed step other than one can also be used. Often, a fixed step length of 0.5 can greatly improve the odds that the iterative equations will converge. On occasion, a step of 0.1 or 0.2 may be required. In general, the smaller the step, the greater the chance of convergence, although an increasing number of iterations may become necessary.

## Quasi-Likelihood Estimation

Wedderburn (1974) establishes a method of estimation for nonlinear models that makes assumptions only about the first two moments of the observed data. Proceeding much like before, let $\mathbf{Y}=\left(Y_{1}, Y_{2}, \ldots, \mathbf{Y}_{N}\right)^{\prime}$ be a vector of independent observations with expectation $\psi=\left(\psi_{1}, \psi_{2}, \ldots, \psi_{\mathrm{N}}\right)^{\prime}$ and covariance matrix $\phi \mathbf{V}(\psi)=\phi \operatorname{diag}\left\{\mathrm{V}_{1}\left(\psi_{1}\right), \mathrm{V}_{2}\left(\psi_{2}\right)\right.$, $\left.\ldots, \mathrm{V}_{\mathrm{N}}\left(\psi_{\mathrm{N}}\right)\right\}$. Suppose that $\psi$ is related to a p -dimensional parameter vector $\boldsymbol{\beta}=$
$\left(\beta_{1}, \beta_{2}, \ldots, \beta_{\mathrm{p}}\right)^{\prime}$ through an arbitrary (possibly nonlinear) regression model $\psi=\psi(\boldsymbol{\beta})$ such that $\partial^{3} \Psi_{i}(\beta) / \partial \beta_{j}^{3}$ are bounded for $i=1,2, \ldots, N, j=1,2, \ldots, p$, and such that if $\boldsymbol{\beta} \neq \boldsymbol{\beta}^{\prime}$ then $\psi(\boldsymbol{\beta}) \neq \psi\left(\boldsymbol{\beta}^{\prime}\right)$ (that is, assume identifiability of the model). Note, however, that no distributional assumptions about $\mathbf{Y}$ have been made.

Under these conditions, Wedderburn defines the log-quasi-likelihood, or simply the quasi-likelihood, of the $i^{\text {th }}$ observation $\mathrm{Q}_{\mathrm{i}}\left(\psi_{\mathrm{i}} ; \mathrm{y}_{\mathrm{i}}\right)$ by the relation

$$
\begin{equation*}
\frac{\partial Q_{i}}{\partial \psi_{i}}=\frac{y_{i}-\psi_{i}}{\phi V_{i}\left(\psi_{i}\right)} \tag{3.7}
\end{equation*}
$$

so that for the given variance function $V_{i}\left(\psi_{i}\right)$, the function $Q_{i}$ possesses the same property (3.2) uniquely associated with log-likelihoods of probability functions having the form (3.1). Any function $Q_{i}$ satisfying (3.7) may serve as a quasi-likelihood, including functions which are not actual likelihoods; hence, the term quasi-likelihood. In particular, $\mathrm{Q}_{\mathrm{i}}$ cannot correspond to an actual likelihood unless $\mathrm{V}_{\mathrm{i}}\left(\psi_{\mathrm{i}}\right)$ is a variance function of a distribution with probability function satisfying (3.1). McCullagh and Nelder (1989, p. 325) defines $\mathrm{Q}_{\mathrm{i}}$ as

$$
\begin{equation*}
Q_{i}\left(\psi_{i} ; y_{i}\right)=\int_{y_{i}}^{\psi_{i}} \frac{y_{i}-t}{\phi V_{i}(t)} d t \tag{3.8}
\end{equation*}
$$

provided that the integral exists. Note that by the Fundamental Theorem of Calculus, this definition satisfies (3.7).

Under the assumption of independence, and provided that each of the $Q_{i}$ exist, the $\log$-quasi-likelihood of the $N$ observations, as a function of $\beta$, is given by $Q(\beta)=$
$\sum_{i=1}^{\mathrm{N}} \mathrm{Q}_{\mathrm{i}}$ (McCullagh, 1983; McCullagh and Nelder, 1989, p. 325). The vector $\hat{\boldsymbol{\beta}}$ that maximizes $Q(\beta)$, that is, provides the solution of $\partial Q(\beta) / \partial \beta=0$, can be determined using Fisher scoring. The estimating equations are given in matrix form by

$$
\begin{equation*}
\mathrm{U}(\beta)=\frac{\partial \mathbf{Q}(\beta)}{\partial \beta}=\mathbf{D}^{\prime} \mathbf{V}^{-1}(\mathbf{y}-\psi(\beta)) / \phi \tag{3.9}
\end{equation*}
$$

where $\mathbf{D}$ has full rank with elements $\mathrm{d}_{\mathrm{ij}}=\partial \psi_{\mathrm{i}} / \partial \boldsymbol{\beta}_{\mathrm{j}}$ and the $(\mathrm{t}+1)^{\text {th }}$ estimate of $\boldsymbol{\beta}$ is given as

$$
\begin{equation*}
\boldsymbol{\beta}^{(t+1)}=\beta^{(t)}+\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1} \mathbf{D}^{\prime} \mathbf{V}^{-1}\left(\mathbf{y}-\psi\left(\boldsymbol{\beta}^{(t)}\right)\right) \tag{3.10}
\end{equation*}
$$

where current estimates of $\mathbf{D}$ and $\mathbf{V}$ are obtained from $\beta^{(t)}$ as before. The vector (3.9) is commonly called the quasi-score vector. It is of interest to note that the estimating equations (3.9) do not explicitly require that $Q(\beta)$ exist as a function (McCullagh, 1986).

For the particular case where $V_{i}(\bullet)$ is constant for each $i=1,2, \ldots, N,(3.10)$ reduces to the Gauss-Newton method for obtaining the solution $\hat{\beta}$ that minimizes the nonlinear weighted least squares criterion $(\mathbf{y}-\Psi(\beta))^{\prime} \mathbf{V}^{-1}(\mathbf{y}-\Psi(\beta))($ Wedderburn, 1974; McCullagh, 1983, 1986). For the general case where the $\mathrm{V}_{\mathrm{i}}(\bullet)$ are functions of the $\psi_{i}$, (3.10) offers a computationally attractive alternative to the generalized least squares technique discussed by Carroll and Ruppert (1988, pp. 13-15), since the latter approach usually requires several successive applications of an iterative nonlinear weighted least squares algorithm. When the observation vector $\mathbf{Y}$ represents a sample from a distribution
with probability function satisfying (3.1), quasi- and maximum-likelihood estimation coincide.

Asymptotic Properties of the Maximum- and Quasi-Likelihood Estimators

A convenient by-product of the Newton-Raphson and Fisher scoring algorithms for maximum-likelihood estimation is that estimated covariance matrices of $\hat{\boldsymbol{\beta}}$ are available upon convergence. For Newton-Raphson, this matrix is the iterated solution for $-\mathbf{H}^{-1}$, once a suitable estimate of $\phi$ is obtained (if necessary) (Judge, et al., 1988, pp. 519-527; Agresti, 1990, p. 116). For Fisher scoring, $\mathbf{I n f}^{-1}=-(\mathbf{E}(\mathbf{H}))^{-1}=\phi\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1}$ is the asymptotic covariance matrix of $\hat{\boldsymbol{\beta}}$ (Judge, et al., pp. 521-523; Agresti, p. 451; Eliason, 1993, p. 40). Wedderburn (1974) shows that the asymptotic covariance matrix of the quasi-likelihood estimator $\hat{\boldsymbol{\beta}}$ can similarly be expressed as $\phi\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1}$.

McCullagh (1983) establishes that the desirable asymptotic properties of $\hat{\beta}$ in the context of maximum-likelihood, namely consistency of $\hat{\boldsymbol{\beta}}$ and asymptotic normality of both $\hat{\beta}$ and $U(\beta)$, can be applied to quasi-likelihood under the model and moment assumptions of the previous section with the additional requirement that $\frac{1}{\phi \mathrm{~N}}\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)$ has a positive definite limit as $\mathrm{N} \rightarrow \infty$.

For the case where N remains fixed, and the responses $\mathrm{Y}_{\mathrm{i}}, \mathrm{i}=1,2, \ldots, \mathrm{~N}$, correspond, for example, to proportions or counts, these results are contingent on the assumption that the elements of $\frac{1}{\phi}\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)$ increase without limit (McCullagh and

Nelder, 1983, p. 133; 1989, p. 328). This requirement generally holds, at least for $\mathrm{N}>$ p, provided that the number of sample elements $n_{i}$ contributing to each of the $Y_{i}$ increases without bound (McCullagh and Nelder, 1983, pp. 82-83, 133). In particular, assuming that the fitted model is correct, for large $n_{i}$, it follows that $\hat{\boldsymbol{\beta}} \dot{\sim} \mathrm{N}\left(\boldsymbol{\beta}, \phi\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1}\right)$ and $\mathrm{U}(\beta) \dot{\sim} \mathrm{N}\left(\mathbf{0}, \frac{\mathbf{1}}{\phi}\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)\right)$.

The Generalized Linear Model

The algorithms (3.6) and (3.10) may be simplified in terms of iteratively reweighted least squares equations, provided that the nonlinear regression equation $\psi=$ $\psi(\beta)$ can be linearized in $\beta$ via a properly chosen transformation. Let $\mathbf{Y}=$ $\left(\mathrm{Y}_{1}, \mathrm{Y}_{2}, \ldots, \mathrm{Y}_{\mathrm{N}}\right)^{\prime}$ be a vector of independent observations with expectation $\psi=$ $\left(\psi_{1}, \psi_{2}, \ldots, \psi_{\mathrm{N}}\right)^{\prime}$ and covariance matrix $\phi \mathbf{V}(\psi)=\phi \operatorname{diag}\left\{\mathbf{V}_{1}\left(\psi_{1}\right), \mathrm{V}_{2}\left(\psi_{2}\right), \ldots, \mathbf{V}_{\mathrm{N}}\left(\psi_{\mathrm{N}}\right)\right\}$, and suppose that there exists a monotone, differentiable function $g(\bullet)$ relating $\psi_{\mathrm{i}}$ to a pdimensional parameter vector $\beta=\left(\beta_{1}, \beta_{2}, \ldots, \beta_{p}\right)^{\prime}$ of the form

$$
\mathrm{g}\left(\psi_{\mathrm{i}}\right)=\mathbf{x}_{\mathrm{i}}^{\prime} \beta, \quad \mathbf{i}=1,2, \ldots, \mathrm{~N},
$$

where $\mathbf{x}_{i}=\left(x_{i 1}, x_{i 2}, \ldots, x_{i p}\right)^{\prime}$ is the $i^{\text {th }}$ set of covariates. A model of $\psi$ in $\beta$ which may be expressed in this form is called a generalized linear model, and $g(\bullet)$ is called a link function. The form of the iterative equations when such a function exists is summarized in the following important theorem, given in Nelder and Wedderburn (1972), Wedderburn
(1974), McCullagh and Nelder (1989, p. 40-43), and Agresti (1990, p. 449-451), and examined by Hillis and Davis (1994).

Theorem 3.1 Let $\mathbf{Y}$ be defined as above with $\mathrm{E}(\mathbf{Y})=\psi$ and $\operatorname{cov}(\mathbf{Y})=\phi \mathbf{V}(\psi)$, and suppose that $\mathrm{g}(\cdot)$ exists as defined above with

$$
\begin{equation*}
g\left(\psi_{i}\right)=\eta_{i}=\mathbf{x}_{i}^{\prime} \beta, i=1,2, \ldots, N \tag{3.11}
\end{equation*}
$$

Then a method equivalent to the iterative equations (3.6) and (3.10) is to calculate repeatedly a weighted linear regression of

$$
z_{i}=g\left(\psi_{i}\right)+g^{\prime}\left(\psi_{i}\right)\left(y_{i}-\psi_{i}\right)
$$

on $x_{i}=\left(x_{i 1}, x_{i 2}, \ldots, x_{i p}\right)^{\prime}$ using weight

$$
\mathbf{w}_{\mathrm{i}}=\left[g^{\prime}\left(\psi_{\mathrm{i}}\right)\right]^{-2}\left[\mathrm{~V}_{\mathrm{i}}\left(\psi_{\mathrm{i}}\right)\right]^{-1}
$$

for $i=1,2, \ldots, N$, where the current estimates of $\psi_{i}$ are computed from the current estimates of $\beta_{1}, \beta_{2}, \ldots, \beta_{p}$.

Proof From (3.6) and (3.10), the $(\mathbf{t}+1)^{\text {th }}$ estimate of $\beta$ is given by

$$
\beta^{(t+1)}=\beta^{(t)}+\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1} \mathbf{D}^{\prime} \mathbf{V}^{-1}\left(\mathbf{y}-\psi\left(\boldsymbol{\beta}^{(t)}\right)\right)
$$

where $\mathbf{D}$ has elements $\mathbf{d}_{\mathrm{ij}}=\partial \psi_{\mathrm{i}} / \partial \beta_{\mathrm{j}}$. Multiplying through by $\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}$ gives

$$
\begin{equation*}
\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right) \boldsymbol{\beta}^{(t+1)}=\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right) \boldsymbol{\beta}^{(t)}+\mathbf{D}^{\prime} \mathbf{V}^{-1}\left(\mathbf{y}-\psi\left(\boldsymbol{\beta}^{(t)}\right)\right) \tag{3.12}
\end{equation*}
$$

However, from (3.11), it follows that

$$
\frac{\partial \psi_{i}}{\partial \beta_{j}}=\frac{\partial \psi_{i}}{\partial \eta_{i}} \frac{\partial \eta_{i}}{\partial \beta_{j}}=\frac{1}{\mathbf{g}^{\prime}\left(\psi_{i}\right)} \mathbf{x}_{\mathrm{ij}}
$$

Hence, $\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}=\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}$, where $\mathbf{X}$ is an $\mathrm{N} x \mathrm{p}$ matrix of full rank having elements $\mathrm{x}_{\mathrm{ij}}$ and
where

$$
\begin{aligned}
\mathbf{W} & =\operatorname{diag}\left\{\left[\mathrm{g}^{\prime}\left(\psi_{1}\right)\right]^{-2}\left[\mathrm{~V}_{1}\left(\psi_{1}\right)\right]^{-1}, \ldots,\left[\mathrm{~g}^{\prime}\left(\psi_{\mathrm{N}}\right)\right]^{-2}\left[\mathrm{~V}_{\mathrm{N}}\left(\psi_{\mathrm{N}}\right)\right]^{-1}\right\} \\
& =\operatorname{diag}\left\{\mathbf{w}_{1}, \mathbf{w}_{2}, \ldots \mathbf{w}_{\mathrm{N}}\right\},
\end{aligned}
$$

evaluated at $\boldsymbol{\beta}^{(t)}$. Further, $\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right) \boldsymbol{\beta}^{(t)}$ is a vector, say $\mathbf{u}$, having elements

$$
u_{k}=\sum_{j=1}^{p} \sum_{i=1}^{N} \frac{\mathbf{x}_{i \mathrm{i}} \mathbf{x}_{\mathrm{ij}}}{\mathrm{~V}_{\mathrm{i}}\left(\psi_{\mathrm{i}}^{(\mathrm{t})}\right)} \frac{1}{\left[\mathrm{~g}^{\prime}\left(\psi_{\mathrm{i}}^{(\mathrm{t})}\right)\right]^{2}} \beta_{\mathrm{j}}^{(\mathrm{t})}, \mathrm{k}=1,2, \ldots, \mathrm{p},
$$

and $\mathbf{D}^{\prime} \mathbf{V}^{-1}\left(\mathbf{y}-\psi\left(\boldsymbol{\beta}^{(\mathfrak{t})}\right)\right)$ is a vector, say $\mathbf{v}$, of estimating equations having elements

$$
\mathbf{v}_{\mathrm{k}}=\sum_{\mathrm{i}=1}^{\mathrm{N}} \frac{\left(\mathbf{y}_{\mathrm{i}}-\psi_{\mathrm{i}}^{(\mathrm{t})}\right) \mathbf{x}_{\mathrm{ik}}}{\mathrm{~g}^{\prime}\left(\psi_{\mathrm{i}}^{(\mathrm{t})}\right) \mathrm{V}_{\mathrm{i}}\left(\psi_{\mathrm{i}}^{(\mathrm{t})}\right)}, \mathrm{k}=1,2, \ldots, \mathrm{p}
$$

where $\Psi_{i}^{(t)}=g^{-1}\left(x_{i}^{\prime} \beta^{(t)}\right)$. Adding the vectors on the right-hand side of (3.12), that is,
taking $\mathbf{u}+\mathbf{v}$, gives a vector having elements

$$
\begin{aligned}
u_{k}+v_{k} & =\sum_{i=1}^{N}\left(\sum_{j=1}^{p} \frac{x_{i k} x_{i j}}{V_{i}\left(\psi_{i}^{(t)}\right)} \frac{1}{\left[g^{\prime}\left(\psi_{i}^{(t)}\right)\right]^{2}} \beta_{j}^{(t)}\right)+\frac{\left(y_{i}-\psi_{i}^{(t)}\right) \mathbf{x}_{i k}}{g^{\prime}\left(\psi_{i}^{(t)}\right) V_{i}\left(\psi_{i}^{(t)}\right)} \\
& =\sum_{i=1}^{N}\left[g^{\prime}\left(\psi_{i}^{(t)}\right)\right]^{-2}\left[V_{i}\left(\psi_{i}^{(t)}\right)\right]^{-1} x_{i k}\left[\sum_{j=1}^{p} x_{i j} \beta_{j}^{(t)}+g^{\prime}\left(\psi_{i}^{(t)}\right)\left(y_{i}-\psi_{i}^{(t)}\right)\right] .
\end{aligned}
$$

Hence, $\mathbf{u}+\mathbf{v}=\mathbf{X}^{\prime} \mathbf{W} \mathbf{z}$, where $\mathbf{z}=\left(\mathbf{z}_{1}, \mathbf{z}_{2}, \ldots, \mathbf{z}_{\mathrm{N}}\right)^{\prime}$, and (3.12) may be written as

$$
\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right) \boldsymbol{\beta}^{(t+1)}=\mathbf{X}^{\prime} \mathbf{W} \mathbf{z}
$$

or

$$
\boldsymbol{\beta}^{(t+1)}=\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime} \mathbf{W} \mathbf{z}
$$

An immediate corollary of the theorem is that the asymptotic covariance matrix of $\hat{\boldsymbol{\beta}}$ may be reexpressed as $\phi\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)^{-1}$, which may be estimated using the iterated solution of $\boldsymbol{\beta}$. Further, the estimating equations $\mathbf{D}^{\prime} \mathbf{V}^{-1}(\mathbf{y}-\psi(\boldsymbol{\beta}))$ may be rewritten as

$$
\mathbf{D}^{\prime} \mathbf{V}^{-1}(\mathbf{y}-\psi(\boldsymbol{\beta}))=\mathbf{X}^{\prime} \mathbf{G}^{-1} \mathbf{V}^{-1}(\mathbf{y}-\psi(\boldsymbol{\beta}))=\mathbf{X}^{\prime} \mathbf{G W}(\mathbf{y}-\psi(\boldsymbol{\beta}))
$$

where $\boldsymbol{G}=\operatorname{diag}\left\{\mathrm{g}^{\prime}\left(\psi_{1}\right), \mathrm{g}^{\prime}\left(\psi_{2}\right), \ldots, \mathrm{g}^{\prime}\left(\psi_{\mathrm{N}}\right)\right\}$. Adequate starting values for the $\mathrm{z}_{\mathrm{i}}$ and $w_{\mathrm{i}}$ may be obtained by substituting $y_{i}$ for $\psi_{i}$ (Wedderburn, 1974; McCullagh and Nelder, 1989, p. 41; Agresti, 1990, p. 450). If necessary, a step length $s_{t}$ can be introduced to aid with convergence, in which case the response $z_{i}$ is given by

$$
z_{i}=g\left(\psi_{i}\right)+s_{t} g^{\prime}\left(\psi_{i}\right)\left(y_{i}-\psi_{i}\right) .
$$

If the fitted model is saturated, that is, has as many parameters as observations, then the iteratively reweighted least squares estimates may be computed directly via ordinary least squares. This result holds because weighted and ordinary least squares are equivalent in the saturated case and because observed and predicted responses coincide, so that the starting substitution in the $z_{i}$ is unchanged. Hence, the estimate $\hat{\beta}$ is given in closed form by

$$
\hat{\boldsymbol{\beta}}=\left(\mathbf{X}^{\prime} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime} \mathbf{z}
$$

where $\mathrm{z}=\left(\mathrm{g}\left(\mathrm{y}_{1}\right), \mathrm{g}\left(\mathrm{y}_{2}\right), \ldots, \mathrm{g}\left(\mathrm{y}_{\mathrm{N}}\right)\right)^{\prime}$. The estimated asymptotic covariance matrix is given in closed form by $\phi\left(\mathbf{X}^{\prime} \hat{\mathbf{W}} \mathbf{X}\right)^{-1}$, where $\hat{\mathbf{W}}=\operatorname{diag}\left\{\left[g^{\prime}\left(y_{i}\right)\right]^{-2}\left[V_{i}\left(y_{i}\right)\right]^{-1}\right\}, i=1,2, \ldots$, N.

## Model Diagnostics

Several techniques for examining the adequacy of a model fit made utilizing quasiand, in particular, maximum-likelihood estimation are available. These include the Wald test, the likelihood-ratio test, and the score test. The behavior of these tests has, in large part, been determined by the general asymptotic results of McCullagh (1983).

The Wald Test

Let $\hat{\boldsymbol{\beta}}=\left(\hat{\boldsymbol{\beta}}_{1}^{\prime}, \hat{\boldsymbol{\beta}}_{2}^{\prime}\right)^{\prime}$ be the unrestricted quasi-likelihood estimate of a $\mathrm{p} \times 1$ vector of model parameters with subvector dimensions $\boldsymbol{\beta}_{1}:(\mathrm{p}-\mathrm{q}) \times 1$ and $\boldsymbol{\beta}_{2}: \mathrm{q} \times 1,0<\mathrm{q}<\mathrm{p}<\mathrm{N}$. Then under conditions where $\hat{\beta}$ has an approximate $p$-variate normal distribution with mean $\beta$ and covariance matrix $\phi\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)^{-1}$, or, in the context of a generalized linear model, with covariance matrix $\phi\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)^{-1}$, a Wald-type test can be used (Serfling, 1980, pp. 128-130; Carroll and Ruppert, 1988, pp. 213-214; Judge, et al., 1988, pp. 52, 109110; Eliason, 1993, pp. 34-35).

In particular, a test of $\mathrm{H}_{0}: \boldsymbol{\beta}_{2}=0$, assuming that $\phi=1$, is given by

$$
\begin{equation*}
\hat{\boldsymbol{\beta}}_{2}^{\prime}\left(\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)_{\mathrm{qxa}}^{-1}\right)^{-1} \hat{\boldsymbol{\beta}}_{2}, \tag{3.13}
\end{equation*}
$$

where $\mathbf{W}$ is estimated at $\hat{\boldsymbol{\beta}}$, and the $q \times q$ subscript denotes the $q \times q$ submatrix of $\left(\mathbf{X}^{\prime} \mathbf{W X}\right)^{-1}$ corresponding to $\hat{\boldsymbol{\beta}}_{2}$. Under $\mathrm{H}_{0}$, (3.13) has an approximate $\chi^{2}$ distribution with q degrees of freedom.

McCullagh (1983) discusses the asymptotic behavior of a test of model fit based on a difference of log-quasi-likelihoods which extends a traditional test based on the loglikelihoods of probability distributions having the form (3.1) detailed in Agresti (1990, p. 452).

Let $\mathbf{Y}=\left(\mathrm{Y}_{1}, \mathrm{Y}_{2}, \ldots, \mathrm{Y}_{\mathrm{N}}\right)^{\prime}$ be a vector of independent observations with expectation $\psi=\left(\psi_{1}, \Psi_{2}, \ldots, \Psi_{\mathrm{N}}\right)^{\prime}$ such that the probability function of the $Y_{i}, \mathbf{i}=1,2, \ldots$, N is of the form (3.1), and suppose initially that $\beta=\left(\beta_{1}^{\prime}, \beta_{2}^{\prime}, \beta_{3}^{\prime}\right)^{\prime}$ is an associated $\mathrm{N} \times 1$ parameter vector corresponding to a saturated model, with subvector dimensions $\beta_{1}:(\mathrm{p}-\mathrm{q}) \times 1, \boldsymbol{\beta}_{2}: \mathrm{q} \times 1$, and $\beta_{3}:(\mathrm{N}-\mathrm{p}) \times 1,0<\mathrm{q}<\mathrm{p}<\mathrm{N}$. Let $\theta=\left(\theta_{1}, \theta_{2}, \ldots, \theta_{\mathrm{N}}\right)^{\prime}$ be the vector of natural parameters of the observations. Let $\hat{\theta}=\theta(\hat{\boldsymbol{\beta}})$ denote its estimate in the saturated case, and let $\mathrm{L}(\hat{\boldsymbol{\beta}})$ denote the unrestricted maximum of the log-likelihood.

Suppose, however, without loss of generality, that a model containing only the parameters in $\left(\boldsymbol{\beta}_{1}^{\prime}, \boldsymbol{\beta}_{2}^{\prime}\right)^{\prime}$ is also under consideration. Take $\hat{\boldsymbol{\theta}}_{1,2}=\theta\left(\hat{\boldsymbol{\beta}}_{1,2}\right)$ as the estimate of $\theta$ for this model and $L\left(\hat{\boldsymbol{\beta}}_{1,2}\right)$ as the restricted maximum of the log-likelihood. Letting $\mathbf{a}_{\mathrm{i}}(\phi)=\phi / \mathrm{w}_{\mathrm{i}}$ in (3.1), it follows that

$$
\begin{align*}
-2\left(\mathrm{~L}\left(\hat{\boldsymbol{\beta}}_{1,2}\right)-\mathrm{L}(\hat{\boldsymbol{\beta}})\right) & =2 \sum_{\mathrm{i}=1}^{\mathrm{N}} \mathrm{w}_{\mathrm{i}}\left[\mathrm{y}_{\mathrm{i}}\left(\hat{\theta}_{\mathrm{i}}-\hat{\theta}_{1,2, \mathrm{i}}\right)-\mathrm{b}\left(\hat{\theta}_{\mathrm{i}}\right)+\mathrm{b}\left(\hat{\theta}_{1,2, \mathrm{i}}\right)\right] / \phi  \tag{3.14}\\
& =\mathrm{D}\left(\mathbf{y} ; \hat{\Psi}_{1,2}\right), \text { say }
\end{align*}
$$

where $\hat{\Psi}_{1,2}=\psi\left(\hat{\boldsymbol{\beta}}_{1,2}\right)$ and $\mathbf{y}=\left(\mathrm{y}_{1}, \mathrm{y}_{2}, \ldots, \mathrm{y}_{\mathrm{N}}\right)^{\prime}$. The function $\mathrm{D}\left(\mathbf{y} ; \hat{\Psi}_{1,2}\right)$ is called the scaled deviance and is often employed as a relative measure of the discrepancy of fit of the reduced model (McCullagh and Nelder, 1989, pp. 33-34; Agresti, 1990, p. 452). For the more general quasi-likelihood, using McCullagh and Nelder's definition (3.8), the scaled deviance (3.14) becomes

$$
\mathrm{D}\left(\mathbf{y} ; \hat{\psi}_{1,2}\right)=-2\left[\mathrm{Q}\left(\hat{\beta}_{1,2}\right)-\mathrm{Q}(\hat{\beta})\right]=-2 \mathrm{Q}\left(\hat{\beta}_{1,2}\right)
$$

In certain cases to be discussed shortly, the distribution of the scaled deviance under the null hypothesis that the reduced model is correct may be approximated by a $\chi^{2}$ distribution with $(N-p)$ degrees of freedom.

Suppose for the moment, however, without loss of generality, that two reduced models, one containing the parameters $\left(\beta_{1}^{\prime}, \beta_{2}^{\prime}\right)^{\prime}$ and the other containing only the parameters $\beta_{1}$, are to be compared. Take $\hat{\theta}_{1}=\theta\left(\hat{\boldsymbol{\beta}}_{1}\right)$ as the estimate of $\theta$ in the latter case and $\mathrm{L}\left(\hat{\boldsymbol{\beta}}_{1}\right)$ as the corresponding restricted maximum. Then, letting $\mathrm{D}\left(\mathbf{y} ; \hat{\psi}_{1}\right)=$ $-2\left(L\left(\hat{\boldsymbol{\beta}}_{1}\right)-\mathrm{L}(\hat{\boldsymbol{\beta}})\right)$ be the corresponding scaled deviance for the latter model, it follows that the difference

$$
\begin{equation*}
\mathrm{D}\left(\mathbf{y} ; \hat{\Psi}_{1}\right)-\mathrm{D}\left(\mathbf{y} ; \hat{\Psi}_{1,2}\right)=2 \sum_{\mathrm{i}=1}^{\mathrm{N}} \mathrm{w}_{\mathrm{i}}\left[\mathrm{y}_{\mathrm{i}}\left(\hat{\boldsymbol{\theta}}_{1,2, \mathrm{i}}-\hat{\theta}_{1, \mathrm{i}}\right)-\mathrm{b}\left(\hat{\theta}_{1,2, \mathrm{i}}\right)+\mathrm{b}\left(\hat{\theta}_{1, \mathrm{i}}\right)\right] / \phi \tag{3.15}
\end{equation*}
$$

also has the form of the scaled deviance as in (3.14). McCullagh shows that under the general model and moment assumptions for quasi- and, hence, maximum-likelihood estimation, if $\frac{1}{\phi N}\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)$ has a positive definite limit as $N \rightarrow \infty$ (or all $\mathbf{n}_{i} \rightarrow \infty$ for fixed

N ), then the difference (3.15) has a limiting $\chi^{2}$ distribution with q degrees of freedom, the difference in the number of parameters between the reduced models, under $\mathrm{H}_{0}: \boldsymbol{\beta}_{2}=\mathbf{0}$ (see also Silvey, 1975, pp. 112-114, and McCullagh and Nelder, 1989, pp. 118-119).

The asymptotic behavior of the scaled deviance itself, however, may be determined only under certain restrictions. Results reported by McCullagh and Nelder (1983, pp. 8283,$133 ; 1989$, pp. 118-119) suggest that, for fixed $N$, with all $n_{i} \rightarrow \infty$, the scaled deviance can generally be approximated by a $\chi^{2}$ distribution, although a detailed theory is apparently unavailable. Conversely, the approximation appears to be generally invalid as $\mathrm{N} \rightarrow \infty$ except when the observations are drawn from normal distributions (McCullagh and Nelder, 1989, p. 36). Evidently, the requirement that all $\mathbf{n}_{\mathrm{i}} \rightarrow \infty$ is not considered by either Bennett (1976) or Shafer and Sullivan (1986) in the development of their (scaled deviance) tests, which utilize a fixed N .

## The Score Test

Let $\widetilde{\boldsymbol{\beta}}=\left(\widetilde{\boldsymbol{\beta}}_{1}^{\prime}, 0^{\prime}\right)^{\prime}$ be the restricted quasi-likelihood estimate of a $p \times 1$ vector of model parameters $\beta=\left(\beta_{1}^{\prime}, \beta_{2}^{\prime}\right)^{\prime}$ with subvector dimensions $\beta_{1}:(p-q) \times 1$ and $\beta_{2}: q \times 1$, $0<\mathrm{q}<\mathrm{p}<\mathrm{N}$ under the hypothesis $\mathrm{H}_{0}: \boldsymbol{\beta}_{2}=\mathbf{0}$. Then under conditions where $\mathrm{U}(\boldsymbol{\beta})$ has an approximate p -variate normal distribution with mean 0 and covariance matrix $\frac{1}{\phi}\left(\mathbf{D}^{\prime} \mathbf{V}^{-1} \mathbf{D}\right)$, or, in the context of a generalized linear model, with covariance matrix $\frac{1}{\phi}\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)$, a score test can be used (Rao, 1973, pp. 418-420; Serfling, 1980, pp. 156158; McCullagh, 1986; Fahrmeir, 1987; Carroll and Ruppert, 1988, pp. 215-216).

In particular, a test of $\mathrm{H}_{0}: \beta_{2}=0$, assuming that $\phi=1$, is given by

$$
\begin{equation*}
[\mathrm{U}(\widetilde{\beta})]^{\prime}\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)^{-1}[\mathrm{U}(\widetilde{\beta})] \tag{3.16}
\end{equation*}
$$

where $\mathbf{W}$ and $\mathrm{U}(\widetilde{\boldsymbol{\beta}})$, the quasi-score vector of estimating equations, are both evaluated at $\widetilde{\boldsymbol{\beta}}$. Under $\mathrm{H}_{\mathrm{o}}$, (3.16) has an approximate $\chi^{2}$ distribution with q degrees of freedom.

## Tests for the Saturated Model

Although McCullagh and Nelder $(1983,1989)$ effectively argue that the scaled deviance itself can, for fixed $N$ and $n_{i} \rightarrow \infty$, be used as a test of fit of a reduced model versus a saturated model, there is little discussion in the literature of the asymptotic behavior of the Wald and score tests in this same scenario. However, given the form of the direct estimate of $\hat{\boldsymbol{\beta}}$ in the saturated generalized linear model, for the responses considered in the next chapter, the results of Serfling (1980, pp. 24-25, 118, 128-130) provide for the asymptotic normality of $\hat{\boldsymbol{\beta}}$ and the large-sample distribution of the Wald test.

## CHAPTER FOUR

## THE MODELLING APPROACH

In this chapter, a proper form for a factorial model of the population CV is proposed. In the context of each of the approximate distributions discussed in Chapter Two, the proposed multiplicative model is shown to satisfy the form of the generalized linear model reviewed in Chapter Three, and the corresponding iteratively reweighted least squares equations for estimating its parameters are established. In addition, a form for the iterative equations for an additive model is also suggested, and the equivalence of some associated one-factor model diagnostics to several of the one-factor tests currently in the literature is shown.

## Choice of Model

In contrast with the one-factor tests discussed in the review of literature, a model of the population CV in a factorial experiment must accommodate the fact that additive restrictions may not adequately describe interactions and main effects. Models of the $\mu_{\mathrm{i}}$ in classical analysis of variance are typically linear, for example, under the often implicit assumption that the $\mu_{\mathrm{i}}$ may take any value on the real number line. However, the population CV is, by assumption, strictly positive, suggesting that multiplicative models are more appropriate.

Some justification for this argument is provided by McCullagh and Nelder (1989) and Eliason (1993). In the notation of Chapter Three, for models with a gammadistributed response $\mathbf{Y}=\left(\mathrm{Y}_{1}, \mathrm{Y}_{2}, \ldots, \mathrm{Y}_{\mathrm{N}}\right)^{\prime}, \mathbf{M c C u l l a g h}$ and $\operatorname{Nelder}$ (p. 286) argues that an appropriate model for the mean vector $\psi=\left(\psi_{1}, \psi_{2}, \ldots, \psi_{N}\right)^{\prime}$ based on a p-dimensional parameter vector $\beta=\left(\beta_{1}, \beta_{2}, \ldots, \beta_{p}\right)^{\prime}$ is the multiplicative model

$$
\psi_{i}=\exp \left(\mathbf{x}_{\mathbf{i}}^{\prime} \boldsymbol{\beta}\right), \mathbf{i}=1,2, \ldots, \mathbf{N}
$$

where $\mathbf{x}_{\mathrm{i}}=\left(\mathrm{x}_{\mathrm{i} 1}, \mathrm{x}_{\mathrm{i} 2}, \ldots, \mathrm{x}_{\mathrm{ip}}\right)^{\prime}$ is the $\mathrm{i}^{\text {th }}$ set of covariate values. Similarly, Eliason (pp. 2223, 47-48) argues for such a model for gamma-distributed responses because of the restriction of the range of the $\psi_{i}$ to positive values.

If it is assumed that the dispersion parameter $\phi$ may vary from observation to observation, then the dispersion vector $\phi=\left(\phi_{1}, \phi_{2}, \ldots, \phi_{\mathrm{N}}\right)^{\prime}$ can likewise be modelled. Eliason (pp. 22-23) notes that since the parameters of $\phi$ cannot be negative, the corresponding model structure should reflect this fact and not allow for unrealistic, that is, negative, values.

Hence, a model of the population CV in a factorial experiment may be argued in the following way. Take a collection of $C V s R_{1}, \mathbf{R}_{2}, \ldots, \mathbf{R}_{k}$ of normal populations, where, for convenience, a single subscript is used, but where any number of associated fixed factors may be supposed. Assume that the $\mathrm{i}^{\text {th }}$ population has mean $\mu_{\mathrm{i}}>0$ and variance $\sigma_{i}^{2}$, so that $R_{i}=\sigma_{i} / \mu_{i}, i=1,2, \ldots, k$. An appropriate model structure for the $\mu_{i}$ is then

$$
\mu_{i}=\exp \left(\mathbf{x}_{\mathbf{i}}^{\prime} \alpha\right), \mathbf{i}=1,2, \ldots, k
$$

where $\alpha=\left(\alpha_{1}, \alpha_{2}, \ldots, \alpha_{p}\right)^{\prime}$ is a parameter vector of fixed factor effects $(p \leq k)$ and $\mathbf{x}_{i}=$ $\left(\mathrm{x}_{\mathrm{i} 1}, \mathrm{x}_{\mathrm{i} 2}, \ldots, \mathrm{x}_{\mathrm{ip}}\right)^{\prime}$ is the $\mathrm{i}^{\text {th }}$ set of covariate values. For a factorial model, these covariates are properly assigned values of zero or positive or negative one under some identifiability constraint; for example, that the associated parameters summed across any single subscript must equal zero. Similarly, a model for the $\sigma_{i}^{2}$ might be

$$
\sigma_{i}^{2}=\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \gamma\right), \mathbf{i}=1,2, \ldots, \mathbf{k}
$$

where $\gamma=\left(\gamma_{1}, \gamma_{2}, \ldots, \gamma_{\mathrm{p}}\right)^{\prime}$ is the corresponding parameter vector for the variances, so that a model for the $\sigma_{i}$ may be written as

$$
\sigma_{i}=\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \gamma^{*}\right), \mathbf{i}=1,2, \ldots, \mathbf{k}
$$

where $\gamma^{*}=0.5 \gamma$.
Combining these models gives a multiplicative model for the $\mathbf{R}_{i}$ :

$$
\begin{align*}
\mathbf{R}_{\mathbf{i}} & =\frac{\sigma_{\mathbf{i}}}{\mu_{\mathrm{i}}}=\frac{\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \gamma^{*}\right)}{\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \alpha\right)}=\exp \left(\mathbf{x}_{\mathbf{i}}^{\prime}\left(\gamma^{*}-\alpha\right)\right) \\
& =\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \mathbf{\delta}\right), \quad \mathbf{i}=1,2, \ldots, \mathrm{k} \tag{4.1}
\end{align*}
$$

where $\delta=\gamma^{*}-\alpha$. This approach is corroborated for the case of gamma-distributed responses (as opposed to normal) by Eliason (1993, pp. 48-51).

As an example of such a model, suppose that two fixed factors, A and B, with a total of $a$ and $b$ levels, respectively, are arranged in a factorial experiment. Then model (4.1) may initially be expressed in the form

$$
\mathbf{R}_{\mathrm{ij}}=\exp \left(\mathbf{R}^{*}+\alpha_{\mathrm{i}}+\beta_{\mathrm{j}}+(\alpha \beta)_{\mathrm{ij}}\right), \mathrm{i}=1,2, \ldots, a, \mathrm{j}=1,2, \ldots, b,
$$

where $\exp \left(\mathrm{R}^{*}\right)$ is the overall population $C V, \exp \left(\alpha_{i}\right)$ is the multiplicative effect caused by the $i^{\text {th }}$ level of $A, \exp \left(\beta_{j}\right)$ is the multiplicative effect caused by the $\mathrm{j}^{\text {th }}$ level of $B$, and the terms $\exp \left((\alpha \beta)_{\mathrm{ij}}\right)$ describe the multiplicative effect caused by an interaction between A and B. In order to estimate the model, an identifiability constraint that, say, $\sum_{i=1}^{\mathrm{a}} \alpha_{\mathrm{i}}=\sum_{\mathrm{j}=1}^{\mathrm{b}} \beta_{\mathrm{j}}=$ $\sum_{\mathrm{i}=1}^{\mathrm{a}}(\alpha \beta)_{\mathrm{ij}}=\sum_{\mathrm{j}=1}^{\mathrm{b}}(\alpha \beta)_{\mathrm{ij}}=0$ is also imposed.

The relationship between the parameters of (4.1) and those of models of the $\mu_{i}$ and the $\sigma_{i}$ demonstrates one of the traditional criticisms of the CV, namely, that simultaneous factor effects on both the mean and standard deviation which are of equal magnitude leave the CV unchanged. Hence, a factor declared not to be significant in (4.1) might have no effect on either the mean or the standard deviation, or the same effect on both.

## The Model-Fitting Algorithm

Suppose, now, that independent random samples of size $n_{i}$ are drawn from each of the $k$ normal populations, and that the sample $C V s r_{i}=S_{i} / \bar{X}_{i}$ and $r_{n, i}=S_{n, i} / \bar{X}_{i}$ are computed, where, as before, $\mathrm{S}_{\mathrm{i}}^{2}$ and $\mathrm{S}_{\mathrm{n}, \mathrm{i}}^{2}$ are the unbiased and maximum-likelihood estimates of $\sigma_{i}^{2}$, respectively. Further, suppose that $R_{i} \in(0,1 / 3), i=1,2, \ldots, k$, that is, that each of the $k$ populations essentially consists of positive values. Although this restriction is not made in the literature except in the context of McKay's approximation, it is largely consistent with the suggestion by Payton (1997) that the populations be of the ratio type and will be assumed throughout the remainder of this thesis.

## McKay's and David's Approximations

According to David's approximation, $\mathrm{h}\left(\mathrm{r}_{\mathrm{i}}\right)$ is distributed approximately gamma
with expectation $h\left(R_{i}\right)$ and index $\left(n_{i}-1\right) / 2$, so that $\operatorname{Var}\left(h\left(r_{i}\right)\right) \approx \frac{2\left[h\left(R_{i}\right)\right]^{2}}{n_{i}-1}=V_{i}\left(h\left(R_{i}\right)\right)$
(taking $\phi=1$ ). Supposing the model (4.1) for the $R_{i}$ gives, as a model for the $h\left(R_{i}\right)$,

$$
h\left(\mathbf{R}_{\mathrm{i}}\right)=\mathrm{h}\left(\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \delta\right)\right), \mathrm{i}=1,2, \ldots, \mathrm{k}
$$

for which a linearizing transformation is

$$
\begin{equation*}
\log h^{-1}\left(h\left(R_{i}\right)\right)=x_{i}^{\prime} \delta \tag{4.2}
\end{equation*}
$$

Model (4.2) is a generalized linear model of the $h\left(R_{i}\right)$ with link function $\log h^{-1}(\bullet)$, but in the parameters of the original model of the $\mathbf{R}_{\mathbf{i}}$, so that estimating (4.2) simultaneously estimates (4.1). Additionally, for $0<x<1$,

$$
\log h^{-1}(x)=\log \left(\frac{x}{1-x}\right)^{1 / 2}=\frac{1}{2} \log \left(\frac{x}{1-x}\right)=\frac{1}{2} \operatorname{logit}(x)
$$

so that (4.2) also has the form of a logit model but with a gamma-distributed response.
As provided by Theorem 3.1, iteratively reweighted least squares may be employed to fit (4.2). Letting $\mathbf{R}_{\mathrm{i}}^{*}=\mathrm{h}\left(\mathrm{R}_{\mathrm{i}}\right)$ and $\mathrm{r}_{\mathrm{i}}^{*}=\mathrm{h}\left(\mathrm{r}_{\mathrm{i}}\right)$, it follows that

$$
\begin{align*}
z_{i} & =\log h^{-1}\left(\mathbf{R}_{i}^{*}\right)+\frac{d\left(\log h^{-1}\left(R_{i}^{*}\right)\right)}{d R_{i}^{*}}\left(r_{i}^{*}-R_{i}^{*}\right) \\
& =\log h^{-1}\left(R_{i}^{*}\right)+\frac{r_{i}^{*}-R_{i}^{*}}{2 R_{i}^{*}\left(1-R_{i}^{*}\right)}, \tag{4.3}
\end{align*}
$$

and

$$
\begin{align*}
\mathbf{w}_{\mathrm{i}} & =\left[\frac{\mathrm{d}\left(\log \mathrm{~h}^{-1}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)\right)}{d \mathbf{R}_{\mathrm{i}}^{*}}\right]^{-2}\left[\mathrm{~V}_{\mathrm{i}}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)\right]^{-1}=\left[\frac{1}{2 \mathbf{R}_{\mathrm{i}}^{*}\left(1-\mathbf{R}_{\mathrm{i}}^{*}\right)}\right]^{-2}\left[\frac{2\left(\mathbf{R}_{\mathrm{i}}^{*}\right)^{2}}{\mathbf{n}_{\mathrm{i}}-1}\right]^{-1} \\
& =2\left(\mathbf{n}_{\mathrm{i}}-1\right)\left(1-\mathbf{R}_{\mathrm{i}}^{*}\right)^{2} . \tag{4.4}
\end{align*}
$$

Appropriate starting values for $z_{i}$ and $w_{i}$ may be obtained by substituting $r_{i}^{*}$ for $\mathbf{R}_{i}^{*}$ in (4.3) and (4.4). Given that the $t^{\text {th }}$ iteration has been made and that the $\mathrm{t}^{\text {th }}$ estimate $\delta^{(t)}$ has been obtained, the $(t+1)^{\text {th }}$ estimate of $\delta$ can be computed after the substitution of $\left(\mathbf{R}_{i}^{*}\right)^{(t)}$ $=\mathrm{h}\left(\exp \left(\mathbf{x}_{\mathbf{i}}^{\prime} \boldsymbol{\delta}^{(t)}\right)\right)$ into (4.3) and (4.4).

If the alternative approximation of McKay is used, then $\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{n, i}\right)$ is supposed to be distributed approximately gamma with expectation $h\left(R_{i}\right)$ and index $\left(n_{i}-1\right) / 2$. Hence, $r_{n, i}^{*}=\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{n, i}\right)$ may be substituted in $z_{i}$ and $w_{i}$ in place of $r_{i}^{*}$.

Upon convergence of the iteratively reweighted least squares algorithm to the maximum-likelihood estimate $\hat{\delta}$, any of the Wald test, the likelihood-ratio test, or the score test may be used to determine the significance of interactions and main effects.

In order to construct the likelihood-ratio test, it is necessary to know the form of the scaled deviance. By the parameterization given in (3.1), the approximate distributions of McKay and David give

$$
\theta_{i}=-\frac{1}{h\left(\mathbf{R}_{i}\right)}=-\frac{1}{\mathbf{R}_{i}^{*}}, \quad b\left(\theta_{i}\right)=\log h\left(R_{i}\right)=\log R_{i}^{*}
$$

with $\phi=1$ and $\mathrm{w}_{\mathrm{i}}=\left(\mathrm{n}_{\mathrm{i}}-1\right) / 2, \mathrm{i}=1,2, \ldots, \mathrm{k}$. Hence, by (3.14) the scaled deviance associated with a fitted model giving $\hat{\mathbf{R}}_{\mathrm{i}}^{*}=\mathrm{h}\left(\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \hat{\delta}\right)\right)$ in terms of David's
approximation, with $\mathbf{r}^{*}=\left(\mathrm{r}_{1}^{*}, \mathrm{r}_{2}^{*}, \ldots, \mathrm{r}_{\mathbf{k}}^{*}\right)^{\prime}$ and $\hat{\mathbf{R}}^{*}=\left(\hat{\mathbf{R}}_{1}^{*}, \hat{\mathbf{R}}_{2}^{*}, \ldots, \hat{\mathbf{R}}_{\mathbf{k}}^{*}\right)^{\prime}$, is

$$
\begin{aligned}
D\left(\mathbf{r}^{*} ; \hat{\mathbf{R}}^{*}\right) & =2 \sum_{i=1}^{k}\left(\frac{n_{i}-1}{2}\right)\left[r_{i}^{*}\left(-\frac{1}{r_{i}^{*}}+\frac{1}{\hat{\mathbf{R}}_{i}^{*}}\right)-\log r_{i}^{*}+\log \hat{R}_{i}^{*}\right] \\
& =-\sum_{i=1}^{k}\left(n_{i}-1\right)\left[\log \left(\frac{r_{i}^{*}}{\hat{\mathbf{R}}_{i}^{*}}\right)-\left(\frac{r_{i}^{*}-\hat{\mathbf{R}}_{i}^{*}}{\hat{\mathbf{R}}_{i}^{*}}\right)\right]
\end{aligned}
$$

(McCullagh and Nelder, 1989, p. 290). For McKay's approximation, $\mathrm{r}_{\mathrm{n}, \mathrm{i}}^{*}$ should be substituted for $r_{i}^{*}$ in the scaled deviance.

## Iglewicz and Myers' Approximation

According to Iglewicz and Myers' approximation, $\mathrm{r}_{\mathrm{i}}$ is distributed approximately normal with mean $R_{i}$ and variance $\left(\frac{R_{i}^{2}}{n_{i}}\right)\left(R_{i}^{2}+\frac{1}{2}\right)=V_{i}\left(R_{i}\right)$ (taking $\phi=1$ ). However, the small-sample behavior of this approximation is inferior to that of McKay's and David's approximations, suggesting that the incorporation of the normal likelihood into the model estimation process here is less desirable than was the previous use of the gamma likelihood. Further, when the variance of a normal distribution is a function of its mean, the probability function no longer has the form (3.1), so that maximum-likelihood estimation via iteratively reweighted least squares is not possible. Carroll and Ruppert ( $1988, \mathrm{pp}$. 21-23) suggests that generalized least squares estimation, of which quasilikelihood estimation is a special case, is generally preferred in these settings. Since quasilikelihood estimation may be achieved through the same least squares process used to fit models for the McKay's and David's approximations, an opportunity to construct a single
algorithm which incorporates all three approximations is available, provided that a model of the $\mathbf{R}_{\mathbf{i}}$ in the context of the Iglewicz and Myers' approximation may be expressed as a generalized linear model.

This is easily achieved since, under the Iglewicz and Myers' approximation, the $r_{i}$ have expectation $\mathbf{R}_{i}$, and a $\log$ transformation of (4.1) gives the desired form. Specifically,

$$
\begin{equation*}
\log R_{i}=\mathbf{x}_{\mathrm{i}}^{\prime} \boldsymbol{\delta} \tag{4.5}
\end{equation*}
$$

which has the structure of a log-linear model. Theorem 3.1 may be applied to obtain the quasi-likelihood estimates of the model parameters in (4.5) with

$$
\begin{align*}
\mathbf{z}_{\mathbf{i}} & =\log \mathbf{R}_{\mathrm{i}}+\frac{\mathrm{d}\left(\log \mathbf{R}_{\mathrm{i}}\right)}{\mathrm{d} \mathbf{R}_{\mathrm{i}}}\left(\mathrm{r}_{\mathrm{i}}-\mathbf{R}_{\mathrm{i}}\right) \\
& =\log \mathbf{R}_{\mathrm{i}}+\frac{\mathbf{r}_{\mathrm{i}}-\mathbf{R}_{\mathrm{i}}}{\mathbf{R}_{\mathrm{i}}} \tag{4.6}
\end{align*}
$$

and

$$
\begin{align*}
\mathbf{w}_{i} & =\left[\frac{d\left(\log \mathbf{R}_{i}\right)}{d \mathbf{R}_{i}}\right]^{-2}\left[\left(\frac{\mathbf{R}_{i}^{2}}{n_{i}}\right)\left(\mathbf{R}_{i}^{2}+\frac{1}{2}\right)\right]^{-1}=\left[\frac{1}{\mathbf{R}_{i}}\right]^{-2}\left[\frac{\mathbf{n}_{i}}{\mathbf{R}_{i}^{2}\left(\mathbf{R}_{i}^{2}+\frac{1}{2}\right)}\right] \\
& =\frac{\mathbf{n}_{i}}{\mathbf{R}_{i}^{2}+\frac{1}{2}} \tag{4.7}
\end{align*}
$$

In this case, appropriate starting values for $z_{i}$ and $w_{i}$ are obtained by substituting $r_{i}$ for $R_{i}$ in (4.6) and (4.7). Subsequently, once the $t^{\text {th }}$ iterated estimate of $\delta$ is obtained, the $(t+1)^{\text {th }}$ is computed by substitution of $\mathbf{R}_{i}^{(t)}=\exp \left(\mathbf{x}_{i}^{\prime} \delta^{(t)}\right)$ into (4.6) and (4.7), with the
process being repeated until convergence to the quasi-likelihood estimate $\hat{\boldsymbol{\delta}}$. Upon convergence, tests of factor effects may be conducted as before.

Using the form of the quasi-likelihood function (3.8), the scaled deviance associated with a fitted model giving $\hat{\mathbf{R}}_{\mathrm{i}}=\exp \left(\mathbf{x}_{\mathrm{i}}^{\prime} \hat{\delta}\right)$, with $\mathbf{r}=\left(\mathbf{r}_{1}, \mathbf{r}_{2}, \ldots, \mathbf{r}_{\mathrm{k}}\right)^{\prime}$ and $\hat{\mathbf{R}}=\left(\hat{\mathbf{R}}_{1}, \hat{\mathbf{R}}_{2}, \ldots, \hat{\mathbf{R}}_{\mathrm{k}}\right)^{\prime}$, is

$$
\mathrm{D}(\mathbf{r} ; \hat{\mathbf{R}})=-2 \sum_{\mathrm{i}=1}^{\mathrm{k}} \mathrm{Q}_{\mathrm{i}}\left(\hat{\mathbf{R}}_{\mathrm{i}} ; \mathbf{r}_{\mathrm{i}}\right)
$$

where

$$
\begin{aligned}
Q_{i}\left(\hat{R}_{i} ; r_{i}\right)= & \int_{r_{i}}^{\hat{R}_{i}} \frac{r_{i}-t}{V_{i}(t)} d t= \\
= & \int_{r_{i}}^{\hat{R}_{i}} \frac{r_{i}-t}{n_{i}}\left(t^{2}+\frac{1}{2}\right) \\
& {\left[\sqrt{2} r_{i}\left(\tan ^{-1}\left(\sqrt{2} r_{i}\right)-\tan ^{-1}\left(\sqrt{2} \hat{\mathbf{R}}_{i}\right)\right)-\left(\frac{r_{i}-\hat{\mathbf{R}}_{i}}{\hat{\mathbf{R}}_{i}}\right)\right] } \\
& +n_{i} \log \left(\frac{r_{i}^{2}\left(\hat{\mathbf{R}}_{i}^{2}+\frac{1}{2}\right)}{\hat{\mathbf{R}}_{i}^{2}\left(r_{i}^{2}+\frac{1}{2}\right)}\right)
\end{aligned}
$$

(Burington, 1947, p. 64).

## Existence and Uniqueness of Estimators

The existence of maximum- and quasi-likelihood estimators in the context of logit and $\log$ links is often a function of whether any of the responses, $y_{i}$, equal zero (McCullagh and Nelder, 1989, p. 117; Agresti, 1990, pp. 245, 249). Because for the current models, such an occurrence is possible only if all of the observations at a given
treatment combination are identical (making the sample CV zero), existence of $\hat{\delta}$ is apparently not an issue. Unfortunately, in the context of these same link functions, the log- and quasi-likelihood surfaces considered above are not strictly concave in $\boldsymbol{\delta}$. In general, this implies that unique maximum- and quasi-likelihood estimates cannot be guaranteed for small $\mathrm{n}_{\mathrm{i}}$ (Wedderburn, 1976; McCullagh, 1983; Fahrmeir and Kaufmann, 1985). However, empirical examination of these likelihood surfaces in simulation suggests that unique maxima do, in fact, exist even for relatively small $\mathbf{n}_{\mathrm{i}}$. In any event, McCullagh shows that for sufficiently large $n_{i}$, the iterative equations will converge to the correct maximum with high probability.

## Model Selection

Although the algorithm for fitting generalized linear models has been established, and diagnostics for determining the adequacy of these models have been summarized, a broader technique for selecting the best model from a collection of potential models is necessary. In a regression setting, several techniques such as forward selection, backward elimination, and stepwise regression are available for determining the best subset of potential covariates. However, for factorial models, the number and type of terms available are limited. Despite this fact, Agresti (1990, pp. 218-222) considers both forward selection and backward elimination in his discussion of log-linear modelling. Nevertheless, he apparently prefers backward elimination, stating, "It is usually safer to delete terms from an overspecified model than to add terms to an underspecified one" (p. 218). For this reason, and also in an attempt to retain much of the spirit of an analysis of
variance for normally-distributed data (which is a special case of the generalized linear model approach discussed here), the backward elimination approach is advocated.

According to this approach, the highest-order interaction of the full or saturated model is tested first, followed in turn, if necessary, by lower-order interactions and main effects according to the standard hierarchy. However, estimated factor effects are generally not independent, so that a reduced model must be iteratively refitted following the deletion of any factor judged not to be significant (McCullagh and Nelder, 1989, pp. 35-36). Further, when testing the significance of several factors with the same hierarchy -for example, the three two-way interactions in a $2^{3}$ or $3^{3}$ factorial -- it is necessary when using the likelihood-ratio or score test to temporarily delete each individual factor in turn in order to build statistics to indicate which, if any, of these are not significant. Examples of model selection are given in Chapter Six.

## Additive Models for Population CVs

Although not consistent with the multiplicative argument given earlier in this chapter, Gupta and Ma's Wald test, for example, expresses relationships among CVs in additive terms. It should be noted that the Wald tests of the significance of the single factor are not the same for additive and multiplicative models (the likelihood-ratio and score tests are unaffected). Because an additive model of the population CV could, conceivably, be desired even in the factorial case, the iterative algorithms for the additive model are given below. In particular, for the one-factor case, a model of the $\mathbf{R}_{\mathbf{i}}$ may be written as $R_{i}=R+\alpha_{i}, i=1,2, \ldots, k$, where $R$ is the overall population $C V$ and $\alpha_{i}$ is the additive effect caused by the $i^{\text {th }}$ factor level. While it is unnecessary to distinguish between
additive and multiplicative models when testing for the presence of the single factor, conceptually, a multiplicative model may be preferred if certain contrasts are desired based on the saturated model (see Chapter Six, Applied Example \#1).

## McKay's and David's Approximations

For McKay's and David's approximations, since a proposed model of the $\mathbf{R}_{i}$ is now $R_{i}=x_{i}^{\prime} \boldsymbol{\delta}$, the associated model of the $h\left(R_{i}\right)$ is given by

$$
h\left(\mathbf{R}_{\mathrm{i}}\right)=\mathrm{h}\left(\mathbf{x}_{\mathrm{i}}^{\prime} \delta\right), \mathrm{i}=1,2, \ldots, \mathrm{k}
$$

and by the generalized linear model

$$
\mathrm{h}^{-1}\left(\mathrm{~h}\left(\mathbf{R}_{\mathrm{i}}\right)\right)=\mathbf{x}_{\mathrm{i}}^{\prime} \delta
$$

Using Theorem 3.1 and letting $R_{i}^{*}=h\left(\mathbf{R}_{i}\right)$ and $r_{i}^{*}=h\left(r_{i}\right)$ as before, David's approximation gives

$$
\begin{align*}
\mathbf{z}_{\mathrm{i}} & =\mathrm{h}^{-1}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)+\frac{\mathrm{d}\left(\mathrm{~h}^{-1}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)\right)}{d \mathrm{R}_{\mathrm{i}}^{*}}\left(\mathrm{r}_{\mathrm{i}}^{*}-\mathbf{R}_{\mathrm{i}}^{*}\right) \\
& =\mathbf{h}^{-1}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)+\frac{\mathrm{r}_{\mathrm{i}}^{*}-\mathbf{R}_{\mathrm{i}}^{*}}{2 \sqrt{\mathbf{R}_{\mathrm{i}}^{*}\left(1-\mathbf{R}_{\mathrm{i}}^{*}\right)^{3}}} \tag{4.8}
\end{align*}
$$

and

$$
\begin{align*}
\mathbf{w}_{\mathrm{i}} & =\left[\frac{\mathrm{d}\left(\mathrm{~h}^{-1}\left(\mathbf{R}_{\mathrm{i}}^{*}\right)\right)}{\mathrm{dR}_{\mathrm{i}}^{*}}\right]^{-2}\left[\mathrm{~V}_{\mathrm{i}}\left(\mathrm{R}_{\mathrm{i}}^{*}\right)\right]^{-1}=\left[\frac{1}{2 \sqrt{\mathbf{R}_{\mathrm{i}}^{*}\left(1-\mathbf{R}_{\mathrm{i}}^{*}\right)^{3}}}\right]^{-2}\left[\frac{2\left(\mathbf{R}_{\mathrm{i}}^{*}\right)^{2}}{\mathbf{n}_{\mathrm{i}}-1}\right]^{-1} \\
& =\frac{2\left(\mathbf{n}_{\mathrm{i}}-1\right)\left(1-\mathbf{R}_{\mathrm{i}}^{*}\right)^{3}}{\mathbf{R}_{\mathrm{i}}^{*}} \tag{4.9}
\end{align*}
$$

As before, appropriate starting values for $z_{i}$ and $w_{i}$ may be obtained by substituting $r_{i}^{*}$ for
$\mathbf{R}_{\mathrm{i}}^{*}$ in (4.8) and (4.9). Further, the $(\mathrm{t}+1)^{\text {th }}$ iterated estimate of $\delta$ can be computed after the substitution of $\left(\mathrm{R}_{\mathrm{i}}^{*}\right)^{(\mathrm{t})}=\mathrm{h}\left(\mathbf{x}_{\mathrm{i}}^{\prime} \boldsymbol{\delta}^{(t)}\right)$ into (4.8) and (4.9). For McKay's approximation, $r_{n, i}^{*}=\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{n, i}\right)$ may be substituted for $r_{i}^{*}$.

## Iglewicz and Myers' Approximation

For Iglewicz and Myers' approximation, the model $R_{i}=\mathbf{x}_{i}^{\prime} \delta$ may be estimated via Theorem 3.1 using simply $z_{i}=r_{i}$ and $w_{i}=\left[\left(\frac{R_{i}^{2}}{n_{i}}\right)\left(R_{i}^{2}+\frac{1}{2}\right)\right]^{-1}$, since the derivative of the link function with respect to $R_{i}$ is one. In this case, only $w_{i}$ is updated after each iteration. Values for the $w_{i}$ are obtained initially by substituting $r_{i}$ for $\mathbf{R}_{i}$ and, after the $t^{\text {th }}$ iteration, by substituting $\mathrm{R}_{\mathrm{i}}^{(\mathrm{t})}=\mathbf{x}_{\mathrm{i}}^{\prime} \boldsymbol{\delta}^{(\mathrm{t})}$.

## Existent One-Factor Tests as Special Cases

In certain one-factor cases, with the appropriate approximation, tests discussed in the review of literature are special cases of model diagnostics discussed in Chapter Three. In particular, Shafer and Sullivan's test, Gupta and Ma's Wald test, and Feltz and Miller's test have a more general form applicable to factorial experiments.

## Shafer and Sullivan's Test

It is easily shown that Shafer and Sullivan's test is equivalent to the likelihoodratio test using McKay's approximation in the one-factor case. For simplicity, let $R_{i}^{*}=h\left(R_{i}\right)$ and $r_{n, i}^{*}=\left(n_{i} /\left(n_{i}-1\right)\right) h\left(r_{n, i}\right)$ as before. Under the null hypothesis $H_{0}: R_{1}=$ $R_{2}=\ldots=R_{k}$, or, equivalently, supposing that the model $R_{i}=R, i=1,2, \ldots, k$ holds, where
$R$ is the common population $C V$, the maximum-likelihood estimate of the single parameter R may be obtained by solving the estimating equation

$$
\sum_{i=1}^{k} \frac{r_{n, i}^{*}-R_{i}^{*}}{\left[\frac{2\left(R_{i}^{*}\right)^{2}}{n_{i}-1}\right]}\left(2 \sqrt{R_{i}^{*}\left(1-R_{i}^{*}\right)^{3}}\right)=0
$$

for $R$. The solution gives, as an estimate of the common predicted mean $R^{*}=h(R)$ under McKay's approximation, $\hat{\mathbf{R}}^{*}=\left(\sum_{\mathrm{i}=1}^{\mathrm{k}}\left(\mathrm{n}_{\mathrm{i}}-1\right) \mathrm{r}_{\mathrm{n}, \mathrm{i}}^{*}\right) /(\mathrm{N}-\mathrm{k})$, where $\mathrm{N}=\sum_{\mathrm{i}} \mathrm{n}_{\mathrm{i}}$. Substituting into the scaled deviance gives

$$
\begin{aligned}
&-\sum_{i=1}^{k}\left(n_{i}-1\right)\left(\log \left(\frac{r_{n, i}^{*}}{\hat{R}^{*}}\right)-\left(\frac{r_{n, i}^{*}-\hat{R}^{*}}{\hat{R}^{*}}\right)\right) \\
&=-\sum_{i=1}^{k}\left(n_{i}-1\right) \log r_{n, i}^{*}+\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(\sum_{i=1}^{k} \frac{\left(n_{i}-1\right) r_{n, i}^{*}}{N-k}\right) \\
&=-\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(\frac{n_{i} h\left(r_{n, i}\right)}{n_{i}-1}\right)+\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(\sum_{i=1}^{k} \frac{n_{i} h\left(r_{n, i}\right)}{N-k}\right) \\
&=-\sum_{i=1}^{k}\left(n_{i}-1\right) \log \left(\frac{n_{i} h\left(r_{n, i}\right)}{n_{i}-1}\right)+(N-k) \log \left(\sum_{i=1}^{k} \frac{n_{i} h\left(r_{n, i}\right)}{N-k}\right),
\end{aligned}
$$

which is distributed as $\chi^{2}$ with $(k-1)$ degrees of freedom under $H_{0}$ for large $n_{i}$. However, this is the Shafer and Sullivan statistic for testing the same hypothesis.

## Gupta and Ma's Wald Test

For the case $\mathrm{k}=2$, it is easily shown that the Wald test using Iglewicz and Myers' approximation is equivalent to Gupta and Ma's Wald test if the approximation is applied
to the $r_{n, i}$ as opposed to the $r_{i}$. Since the decision to use $r_{i}$ in place of $r_{n, i}$ is largely unimportant, this shows that the Gupta and Ma test is also a special case of the current results.

For the model $R_{i}=R+\alpha_{i}, i=1$, 2 , where $R$ is the overall population $C V$ and $\alpha_{i}$ is the deviation due to the $i^{\text {th }}$ factor level, a corresponding model in matrix form, subject to the identifiability constraint $\sum_{i=1}^{2} \alpha_{i}=0$, is

$$
\left[\begin{array}{l}
\mathbf{R}_{1} \\
\mathbf{R}_{2}
\end{array}\right]=\left[\begin{array}{cc}
1 & 1 \\
1 & -1
\end{array}\right]\left[\begin{array}{c}
\mathbf{R} \\
\alpha_{1}
\end{array}\right] .
$$

Because the model is saturated, quasi-likelihood estimates of R and $\alpha_{1}$ may be obtained directly via ordinary least squares as

$$
\left[\begin{array}{c}
\hat{\mathbf{R}} \\
\hat{\alpha}_{1}
\end{array}\right]=\left(\mathbf{X}^{\prime} \mathbf{X}\right)^{-1} \mathbf{X}^{\prime} \mathbf{r}
$$

where $\mathbf{X}=\left[\begin{array}{cc}1 & 1 \\ 1 & -1\end{array}\right]$, and $\mathbf{r}=\left(\mathrm{r}_{\mathrm{n}, 1}, \mathrm{r}_{\mathrm{n}, 2}\right)^{\prime}$. Hence,

$$
\hat{\mathbf{R}}=\frac{1}{2} \mathrm{r}_{\mathrm{n}, 1}+\frac{1}{2} \mathrm{r}_{\mathrm{n}, 2} \text {, and } \quad \hat{\alpha}_{1}=\frac{1}{2} \mathrm{r}_{\mathrm{n}, 1}-\frac{1}{2} \mathrm{r}_{\mathrm{n}, 2} .
$$

The estimated asymptotic covariance matrix of $\left[\begin{array}{c}\hat{\mathbf{R}} \\ \hat{\alpha}_{1}\end{array}\right]$ is given by

$$
\left(\mathbf{X}^{\prime} \hat{\mathbf{W}} \mathbf{X}\right)^{-1}=\frac{1}{4}\left[\begin{array}{ll}
\mathrm{V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)+\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right) & \mathrm{V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)-\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right) \\
\mathrm{V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)-\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right) & \mathrm{V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)+\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right)
\end{array}\right],
$$

where $\hat{\mathbf{W}}=\operatorname{diag}\left\{\left[\frac{r_{n, i}^{2}}{n_{i}}\left(r_{n, i}^{2}+\frac{1}{2}\right)\right]^{-1}\right\}=\operatorname{diag}\left\{\left[V_{i}\left(r_{n, i}\right)\right]^{-1}\right\}, i=1$, 2. Testing the null
hypothesis that $\mathbf{R}_{1}=\mathbf{R}_{2}$ is equivalent to testing $\alpha_{1}=0$, and the Wald test for the latter equality is

$$
\begin{aligned}
\hat{\alpha}_{1}\left[\frac{1}{4}\left(\mathrm{~V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)+\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right)\right)\right]^{-1} \hat{\alpha}_{1} & =\frac{4 \hat{\alpha}_{1}^{2}}{\mathrm{~V}_{1}\left(\mathrm{r}_{\mathrm{n}, 1}\right)+\mathrm{V}_{2}\left(\mathrm{r}_{\mathrm{n}, 2}\right)} \\
& =\frac{\left(\mathrm{r}_{\mathrm{n}, 1}-\mathrm{r}_{\mathrm{n}, 2}\right)^{2}}{\frac{r_{n, 1}^{2}}{\mathrm{n}_{1}}\left(\mathrm{r}_{\mathrm{n}, 1}^{2}+\frac{1}{2}\right)+\frac{r_{n, 2}^{2}}{\mathrm{n}_{2}}\left(\mathrm{r}_{\mathrm{n}, 2}^{2}+\frac{1}{2}\right)},
\end{aligned}
$$

which is distributed as $\chi^{2}$ with one degree of freedom under $H_{0}$ for large $n_{i}$. This is also the Gupta and Ma Wald test for $k=2$. A similar equivalence holds for $k>2$ if the hypothesis $H_{0}: \alpha_{i}=0, i=1,2, \ldots, k-1$ is tested.

## Feltz and Miller's Test

For the case $\mathbf{k}=2$, it is easily shown that the quasi-score test using Iglewicz and Myers' approximation is equivalent to Feltz and Miller's test. Under the null hypothesis that $\mathbf{R}_{1}=\mathbf{R}_{2}=\ldots=\mathbf{R}_{k}$, the model for the $\mathbf{R}_{\mathrm{i}}$ may be written as $\mathbf{R}_{\mathrm{i}}=\mathrm{R}, \mathrm{i}=1,2, \ldots, \mathrm{k}$, where $R$ is the common population $C V$. The restricted quasi-likelihood estimate of the single model parameter R is obtained by solving the estimating equation

$$
\sum_{i=1}^{k} \frac{r_{i}-R_{i}}{\frac{R_{i}^{2}}{n_{i}}\left(R_{i}^{2}+\frac{1}{2}\right)}=0
$$

which gives $\widetilde{R}=\left(\sum_{i=1}^{k} n_{i} r_{i}\right) / N$, where $N=\sum_{i} n_{i}$. This estimate of $R$ is the weighted average of $\mathrm{r}_{\mathrm{i}}$ given by Feltz and Miller as a reasonable estimate of the common CV under $H_{0}$. Substituting $\widetilde{R}$ into the formula for the quasi-score test for the specific case $k=2$
initially gives

$$
\begin{equation*}
[\mathbf{U}(\widetilde{\mathbf{R}})]^{\prime}\left(\mathbf{X}^{\prime} \widetilde{\mathbf{W}} \mathbf{X}\right)^{-1}[\mathbf{U}(\widetilde{\mathbf{R}})]=\left[(\mathbf{r}-\widetilde{\mathbf{R}})^{\prime} \widetilde{\mathbf{W}} \mathbf{X}\right]\left(\mathbf{X}^{\prime} \widetilde{\mathbf{W}} \mathbf{X}\right)^{-1}\left[\mathbf{X}^{\prime} \tilde{\mathbf{W}}(\mathbf{r}-\widetilde{\mathbf{R}})\right] \tag{4.10}
\end{equation*}
$$

where $\mathbf{X}=\left[\begin{array}{cc}1 & 1 \\ 1 & -1\end{array}\right]$ is the design matrix of the saturated model $\left[\begin{array}{l}\mathbf{R}_{1} \\ \mathbf{R}_{2}\end{array}\right]=\left[\begin{array}{cc}1 & 1 \\ 1 & -1\end{array}\right]\left[\begin{array}{c}\mathbf{R} \\ \alpha_{1}\end{array}\right]$,
$\widetilde{\mathbf{W}}=\operatorname{diag}\left\{\left[\frac{\widetilde{\mathbf{R}}^{2}}{\mathbf{n}_{i}}\left(\widetilde{\mathbf{R}}^{2}+\frac{1}{2}\right)\right]^{-1}\right\}=\operatorname{diag}\left\{\left[\mathrm{V}_{\mathrm{i}}(\widetilde{\mathbf{R}})\right]^{-1}\right\}, \mathrm{i}=1,2$, and where $\mathbf{r}=\left(\mathrm{r}_{1}, \mathrm{r}_{2}\right)^{\prime}$ and $\widetilde{\mathbf{R}}=\left(\widetilde{\mathbf{R}}_{1}, \widetilde{\mathbf{R}}_{2}\right)^{\prime}=(\widetilde{\mathbf{R}}, \widetilde{\mathbf{R}})^{\prime}$. However, (4.10) may be reexpressed as

$$
\begin{aligned}
& {\left[\begin{array}{l}
\frac{r_{1}-\widetilde{R}}{V_{1}(\widetilde{R})}+\frac{r_{2}-\widetilde{R}}{V_{2}(\widetilde{R})} \\
\frac{r_{1}-\widetilde{R}}{V_{1}(\widetilde{R})}-\frac{r_{2}-\widetilde{R}}{V_{2}(\widetilde{R})}
\end{array}\right]^{\prime}\left(\frac{1}{4}\left[\begin{array}{ll}
V_{1}(\widetilde{R})+V_{2}(\widetilde{R}) & V_{1}(\widetilde{R})-V_{2}(\widetilde{R}) \\
V_{1}(\widetilde{R})-V_{2}(\widetilde{R}) & V_{1}(\widetilde{R})+V_{2}(\widetilde{R})
\end{array}\right]\left[\begin{array}{l}
\frac{r_{1}-\widetilde{R}}{V_{1}(\widetilde{R})}+\frac{r_{2}-\widetilde{R}}{V_{2}(\widetilde{R})} \\
\frac{r_{1}-\widetilde{R}}{V_{1}(\widetilde{R})}-\frac{r_{2}-\widetilde{R}}{V_{2}(\widetilde{R})}
\end{array}\right]\right.} \\
& =\frac{\left(r_{1}-\widetilde{R}\right)^{2}}{\mathrm{~V}_{1}(\widetilde{\mathrm{R}})}+\frac{\left(\mathrm{r}_{2}-\widetilde{\mathbf{R}}\right)^{2}}{\mathrm{~V}_{2}(\widetilde{\mathrm{R}})} \\
& =\frac{1}{\widetilde{\mathbf{R}}^{2}\left(\widetilde{\mathbf{R}}^{2}+\frac{1}{2}\right)}\left[\mathbf{n}_{1}\left(\mathrm{r}_{1}-\widetilde{\mathbf{R}}\right)^{2}+\mathbf{n}_{2}\left(\mathrm{r}_{2}-\widetilde{\mathbf{R}}\right)^{2}\right],
\end{aligned}
$$

which is the Feltz and Miller statistic. A similar result holds for $\mathrm{k}>2$ but becomes difficult to demonstrate because of the complexity of $\left(\mathbf{X}^{\prime} \mathbf{W} \mathbf{X}\right)^{-1}$ in closed form.

## Confidence Intervals for Fitted Models

Once the significant interactions and main effects in a fitted factorial model have been determined, confidence intervals for estimated contrasts may be desired. For the multiplicative model (4.1), such contrasts estimate ratios of unknown population CVs
rather than differences, as in normal-theory analysis of variance. If the additive model of the CVs is used, these contrasts will estimate differences.

For simplicity, suppose that two population $\mathbf{C V s}, \mathbf{R}_{1}$ and $\mathbf{R}_{2}$, are to be contrasted, and assume that the multiplicative model (4.1) has been fitted. Note that although a single subscript is used, these CVs may be associated with either main or simple effects of factors. In this context, the unknown ratio of $R_{1}$ and $R_{2}$ may be expressed as

$$
\log \left(\frac{R_{1}}{R_{2}}\right)=\log R_{1}-\log R_{2}=x_{1}^{\prime} \delta-x_{2}^{\prime} \delta=\left(\mathbf{x}_{1}^{\prime}-\mathbf{x}_{2}^{\prime}\right) \delta=\mathbf{x}_{12}^{\prime} \delta
$$

Once the maximum- or quasi-likelihood estimates of $\delta$ are obtained via one of the three approximations under consideration, an asymptotic $100(1-\alpha) \%$ confidence interval for the log-ratio is then
where $z_{\alpha / 2}$ is a value from a standard normal distribution having right-tail probability $\alpha / 2$, and where $\left(\mathbf{X}^{\prime} \hat{\mathbf{W}} \mathbf{X}\right)^{-1}$ is the appropriate estimated asymptotic covariance matrix of $\hat{\boldsymbol{\delta}}$. Denoting the lower and upper endpoints of this interval by $\hat{\mathbf{L}}$ and $\hat{\mathbf{U}}$, respectively, a corresponding $100(1-\alpha) \%$ confidence interval for $R_{1} / R_{2}$ is then given by $(\exp (\hat{\mathrm{L}}), \exp (\hat{\mathrm{U}}))$. Examples of interval estimation are provided in Chapter Six.

For the additive model,

$$
\mathbf{R}_{1}-\mathbf{R}_{2}=\mathbf{x}_{1}^{\prime} \boldsymbol{\delta}-\mathbf{x}_{2}^{\prime} \boldsymbol{\delta}=\left(\mathbf{x}_{1}^{\prime}-\mathbf{x}_{2}^{\prime}\right) \boldsymbol{\delta}=\mathbf{x}_{12}^{\prime} \boldsymbol{\delta}
$$

so that a $100(1-\alpha) \%$ confidence interval for the difference between population CVs may be constructed as

$$
\widehat{\mathbf{R}_{1}-\mathbf{R}_{2}}=\mathbf{x}_{12}^{\prime} \hat{\boldsymbol{\delta}} \pm \mathbf{z}_{\alpha / 2} \sqrt{\mathbf{x}_{12}^{\prime}\left(\mathbf{X}^{\prime} \hat{\mathbf{W}} \mathbf{X}\right)^{-1} \mathbf{x}_{12}},
$$

where $\mathbf{z}_{\alpha / 2}$ and $\left(\mathbf{X}^{\prime} \hat{\mathbf{W}} \mathbf{X}\right)^{-1}$ are defined as before.

## CHAPTER FIVE

## SIMULATION METHODS AND RESULTS

In this chapter, the objectives and methods of the adopted simulation strategy are discussed. Simulation results, as well as their potential ramifications on the overall modelling approach, are summarized. For reference throughout this chapter, tables of simulation results are included in Appendix A. The simulation programs for SAS are included in Appendixes C through F.

## Simulation Objectives

## Asymptotic Behavior of the Scaled Deviance

Since there are apparently no conclusive results pertaining to the asymptotic behavior of the scaled deviance, the sufficiency of large samples in the current modelling context is investigated. In particular, the capability of the scaled deviance as a test of interaction in a $2 \times 2$ factorial experiment is simulated. The corresponding Wald and score tests also are considered.

Asymptotic Behavior of a Difference of Scaled Deviances

Agresti (1990, p. 250) notes that for log-linear models for count data, where the scaled deviance is known to have a limiting $\chi^{2}$ distribution, a difference of scaled
deviances for comparing a reduced model to an intermediate but unsaturated model converges to its limiting distribution more quickly than the scaled deviance, provided that the reduced model holds. This suggests that the use of a difference as a test of significance of, say, a main effect in a $2 \times 2$ factorial model of population CVs may be superior to the required use of the scaled deviance as a test of interaction in the same experiment. The relative behavior of these diagnostics is determined for this case. The corresponding Wald and score tests also are considered.

## Relative Capabilities of Model Diagnostics

The combination of the three approximations under consideration (McKay's, David's, and Iglewicz and Myers') with the three potential diagnostic tests (Wald, likelihood-ratio, and score) results in nine ways of testing the significance of an effect(s) in a fitted factorial model. The relative powers and Type I error rates of these nine tests in the context of the $2 \times 2$ factorial experiment discussed above are investigated. The One-Factor Experiment

For the one-factor experiment, the likelihood-ratio test using McKay's approximation and the Wald and score tests using Iglewicz and Myers' approximation correspond to established tests (see Chapter Four). However, the six remaining tests are new in this context. For this reason, the capabilities of all nine tests in the one-factor experiment are compared. In addition, three other existent tests discussed in the review of literature are simulated.

## Non-Normal Data

If Payton's (1997) suggestion that the CV be associated primarily with ratio-level data is followed, the possibility exists that data will actually be taken from extremely rightskewed populations. To investigate the impact of skewed data, simulated observations are drawn from gamma distributions having CVs marginally within and clearly outside the range $(0,1 / 3)$ of values consistent with the assumption of "ratio-normality".

## Simulation of a $2 \times 2$ Factorial Experiment

In order to assess and compare the capabilities of the approximation-diagnostic combinations under consideration, tests of interaction and a main effect were conducted on normal data that were generated using a $2 \times 2$ multiplicative factorial model of the form

$$
\begin{equation*}
\mathbf{R}_{\mathrm{ij}}=\exp \left(\mathrm{R}^{*}+\alpha_{\mathrm{i}}+\beta_{\mathrm{j}}+(\alpha \beta)_{\mathrm{ij}}\right), \mathrm{i}, \mathrm{j}=1,2, \tag{5.1}
\end{equation*}
$$

where, for identifiability, $\sum_{i=1}^{2} \alpha_{i}=\sum_{j=1}^{2} \beta_{j}=\sum_{i=1}^{2}(\alpha \beta)_{i j}=\sum_{j=1}^{2}(\alpha \beta)_{i j}=0$. For convenience, the data were drawn from normal populations having means $\mu_{\mathrm{ij}}=1$ and standard deviations $\sigma_{\mathrm{ij}}=\mathbf{R}_{\mathrm{ij}}$.

For the simulations, the overall $C V, \exp \left(\mathrm{R}^{*}\right)$, was set at both 0.1 and 0.2 . For an overall $C V$ of 0.1 , tests of interaction were conducted with $\exp \left((\alpha \beta)_{11}\right)$ set to $1,1.1,1.2$, $\ldots, 1.6$, and, for simplicity, with $\alpha_{1}=\beta_{1}=0$. The main-effect tests were conducted only for a single factor. In particular, effect sizes of $\exp \left(\beta_{1}\right)=1,1.1,1.2, \ldots, 1.6$ were considered. In this case, the interaction terms $(\alpha \beta)_{\mathrm{ij}}$ were removed from the generating model so that the main-effect tests could be conducted in the proper context. For
simplicity, $\alpha_{1}$ was set to zero. For an overall CV of 0.2 , tests were conducted on interaction and main effect sizes of $1,1.05,1.1,1.15, \ldots, 1.3$. Smaller sizes were chosen to preserve the range $(0,1 / 3)$ of population CVs of "ratio-normal" distributions.

For an overall CV of 0.1 , equal sample sizes of $10,20,30$, and 50 were taken from each of the $2 \times 2=4$ factor level combinations. Sample size combinations of 10 with 20, 10 with 30,20 with 30 , and 30 with 50 also were considered. For an overall CV of 0.2 , samples with equal sizes of 30,50 , and 100 were drawn, the larger samples reflecting the smaller effect sizes considered. Combinations of 30 with 50 and 50 with 100 also were examined.

For each combination of overall CV, effect type (main or interaction), effect size, and sample size configuration, 10,000 data sets were simulated, and the appropriate effect was tested at the 0.05 level using each of the nine approximation-diagnostic combinations under consideration. On occasion, this strategy produced duplicate simulations when effect sizes were set to one. These simulations were combined to give improved estimated Type I error rates based on 20,000 data sets and are marked in the tables by a single asterisk (*).

## Simulation of a One-Factor Experiment

In order to compare the new approximation-diagnostic combinations in the onefactor case, normal data also were generated from a one-factor multiplicative model having three levels. A multiplicative model was chosen to provide greater flexibility when varying the magnitude of the single factor effect. However, an additive model was actually fitted in the simulation so that Gupta and Ma's Wald test would have the proper
form. In particular, the model

$$
\mathbf{R}_{\mathbf{i}}=\exp \left(\mathbf{R}^{*}+\alpha_{\mathrm{i}}\right), \mathbf{i}=1,2,3
$$

was used to generate the data. Like the $2 \times 2$ factorial model above, data were generated from normal distributions having means $\mu_{i}=1$ and standard deviations $\sigma_{i}=\mathbf{R}_{\mathbf{i}}$. The identifiability constraint $\alpha_{2}=0$ was used. For simplicity, $\alpha_{1}$ was set equal to $-\alpha_{3}$, with $\alpha_{3} \geq 0$. Numerically, this produced $\mathbf{R}_{1} \leq \mathbf{R}_{2} \leq \mathbf{R}_{3}$, with $\mathbf{R}_{2}$ equal to the overall population $\mathbf{C V}, \exp \left(\mathbf{R}^{*}\right)$.

The overall CV was set at both 0.1 and 0.2 . For an overall CV of 0.1 , tests were conducted with $\exp \left(\alpha_{3}\right)=1,1.1,1.2, \ldots, 1.6$. In this case, equal sample sizes of 10,20 , 30 , and 50 were taken, while combinations of 10 with 20,10 with 30,20 with 30 , and 30 with 50 also were considered. For an overall CV of $0.2, \exp \left(\alpha_{3}\right)$ was set at $1,1.05,1.1$, $1.15, \ldots, 1.3$, the smaller effect sizes preserving the "ratio-normal" range of population CVs. Equal sample sizes of 30,50 , and 100 were simulated, as well as combinations of 30 with 50 and 50 with 100.

For each combination of overall CV, effect size, and sample size configuration, 10,000 data sets were simulated. The effect was tested at the 0.05 level using each of the nine approximation-diagnostic combinations under consideration and also using Doornbos and Dijkstra's likelihood-ratio and non-central t tests, and Gupta and Ma's score test. Duplicate simulations for effect sizes of one were combined to give 30,000 data sets to use in assessing the Type I error rate. These are marked by a double asterisk ( ${ }^{(* *)}$ in the tables.

## Simulation of Non-Normal Data

In order to determine the impact of non-normal data, in particular, right-skewed data, on the approximation-diagnostic combinations, observations also were generated from gamma distributions having CVs determined by model (5.1). Since the mean of a gamma distribution is $\lambda$ and the standard deviation is $\frac{\lambda}{\sqrt{v}}$, the corresponding population CV is given by $\frac{\lambda / \sqrt{v}}{\lambda}=\frac{1}{\sqrt{v}}$. For convenience, the data satisfying (5.1) were drawn from gamma distributions having means $\lambda_{i j}=1$ and index parameters $v_{i j}=\frac{1}{\mathrm{R}_{\mathrm{ij}}^{2}}$.

Skewed data were simulated using overall population CVs of 0.3 and 0.6 . Larger overall values were chosen so that the generated data would possess a noticeable level of skewness. Tests of interaction only were conducted with $\exp \left((\alpha \beta)_{11}\right)$ set to $1,1.1,1.2, \ldots$, 1.6 for sample configurations involving sizes of 10,20 , and 30 at both overall CV values. Sample configurations involving sizes of 50 and 100 also were investigated for interaction effect sizes of $1,1.05,1.1,1.15, \ldots, 1.3$ at both overall CV values.

Simulation Results

## The Interaction Test

Tables XV through XXXIX summarize the simulations of the scaled deviance as a test of interaction in a $2 \times 2$ factorial experiment, as well as the corresponding Wald and score tests. For equal sample sizes, Type I error rates tended to be high for all tests except the score tests using McKay's (M) and David's (D) approximations, but tended to
improve as the sample size increased. Type I error rates for Iglewicz and Myers' (IM) approximation were consistently higher than M and D .

Except for the score tests using M and D, Type I error rates were adversely affected by unequal sample sizes, but more so when overall sample sizes were small. In particular, effects of unequal sample sizes were most pronounced for combinations of 10 with 20 and 10 with 30.

For unequal sample sizes, the Wald, likelihood-ratio, and score tests performed comparably when larger samples were drawn from populations with smaller CVs for all approximations, while the Wald test was consistently more powerful than the likelihoodratio and score tests when larger samples were associated with larger CVs. This last pattern was present though less pronounced when sample sizes were evenly split between the "low" and "high" levels of interaction. Overall, the effects of unequal sample sizes were strongest when sample sizes were small (in particular, 10 with 20 and 10 with 30 ).

In general, sample size configurations common to simulations involving overall CVs of 0.1 and 0.2 (all 30, all 50, 30 with 50 ) showed that powers tended to be slightly lower when the overall CV was larger.

## The Main-Effect Test

Tables XL through LXIV summarize the use of a difference of scaled deviances as a test of a main effect in a $2 \times 2$ factorial experiment, as well as the corresponding $\mathbf{W}$ ald and score tests. For both overall CV values and equal sample sizes, the performance of these main-effect tests, based on a single degree of freedom, was virtually identical to the
interaction tests above, which also were based on one degree of freedom. However, Type I error rates were slightly improved.

For unequal sample size configurations, for both overall CV values, the main-effect tests performed better than the interaction tests when large samples were coupled with small population CVs and when sample sizes were split evenly between "low" and 'high" levels for all approximations. On the other hand, the interaction tests performed better when large samples were combined with large CVs. As in other previous cases involving unequal samples, these results were most pronounced when overall sizes were small (in particular, 10 with 20 and 10 with 30). In addition, the main-effect tests were typically more successful than the interaction tests at maintaining the stated Type I error rate when small and disparate sample sizes were used.

## Relative Capabilities of Model Diagnostics

Relative performance among the approximation-diagnostic combinations under consideration was virtually the same for the interaction and main-effect tests. In general, diagnostics using IM tended to have higher power than $M$ or $D$, while $M$ tended to have slightly higher power than D. However, IM also tended to exceed the Type I error rate more often than $\mathbf{M}$ or D .

Among diagnostics associated with a given approximation, when larger samples were associated with smaller population CVs, the likelihood-ratio test tended to have the highest power, followed closely by both the Wald and score tests. When larger samples were associated with larger CVs, the Wald test typically has the highest power, followed closely by the likelihood-ratio test. However, the score test had much lower power when

M or D was used and moderately so when IM was used. This last pattern was also present when sample sizes were unequal but split evenly between "low" and "high" levels of the relevant effect, although the score tests associated with $\mathbf{M}$ and D were more powerful. When sample sizes were equal, all tests and approximations were comparable. The One-Factor Experiment

Tables LXV through CVII summarize the use of the approximation-diagnostic combinations under consideration as tests of the single effect in a one-factor experiment. For equal sample sizes, at both overall CV values, the Type I error rates for IM and Doornbos and Dijkstra's likelihood-ratio test (DDL) were extremely poor but improved as the sample sizes increased. Among all tests, the likelihood-ratio test using IM was the most powerful but had the most difficulty achieving the Type I error rate. Doornbos and Dijkstra's t test (DDT) and Gupta and Ma's score test (GM) consistently had the lowest power but improved as the sample sizes increased.

For one small and two large samples, when the largest samples corresponded to the largest population CVs, the Wald and likelihood-ratio tests using IM were the most powerful. For other configurations involving one small and two large samples, the likelihood-ratio test using IM and DDL were consistently the most powerful. Overall, the score tests using M and D, DDT, and GM preserved the Type I error rate, while the Wald and likelihood-ratio tests using IM and DDL had the worst Type I rates. As overall sample sizes increased, the score test using IM also tended to have a good Type I error rate.

For two small and one large sample, when the single large sample corresponded to the largest population CV, the Wald test using IM was the single most powerful test but had the worst Type I error rate. For other configurations involving two small and one large sample, the likelihood-ratio test using IM and DDL were the most powerful but were among the worst at preserving the Type I rate. Overall, as before, the score tests using M and D, DDT, and GM preserved the Type I error rate and were joined by the score test using IM as overall sample sizes increased.

Among all simulations involving unequal sample size configurations, as sample sizes became more disparate, Type I error rates tended to worsen, but improved as overall sample sizes increased. However, the Wald and likelihood-ratio tests using IM and DDL continued to have difficulty preserving the Type I rate. Among sample size configurations common to both overall CV values, powers tended to be less for an overall CV value of 0.2 as opposed to 0.1 .

## The Interaction Test for Non-Normal Data

Tables CVIII through CXXV summarize the capabilities of the approximationdiagnostic combinations under consideration as tests of interaction in a $2 \times 2$ factorial experiment when the observations belong to right-skewed populations. For an overall CV of 0.3 , which resulted in some population CV values falling outside the range expected for "ratio-normal" distributions, powers of all tests were somewhat lower for every sample size configuration than for "ratio-normal" data. However, except for IM in some small sample cases, the simulated Type I error rates were below the stated 0.05 level.

For an overall CV of 0.6 , powers were substantially lower among all sample size configurations compared to the corresponding tests when the overall CV was at 0.3 . The powers for the score tests summarized in Table CXXIII were particularly poor. However, all Type I error rates attained the stated level. Overall, the likelihood-ratio test using IM retained the most power.

In some cases where the sample sizes were moderately small, the score tests actually decreased in power when an extremely large interaction effect was present! In order to determine if these results were due to sampling error alone, all affected rejection rates were tested for a significant decrease at the 0.05 level, and those found to be significant are bolded in the tables (in particular, tables CXIV, CXV, CXIX, and CXXIII are affected). These results can apparently be attributed to the inability of the approximate likelihood surfaces under consideration to completely incorporate extreme effect sizes associated with right-skewed populations having CVs outside the range expected for "ratio-normal" data.

## Recommendations

For factorial experiments, if sample sizes are equal, the score tests using M and D are preferred. These tests preserve the Type I error rate but have powers comparable to the other approximation-diagnostic combinations for hypotheses involving both saturated and reduced models as indicated by the interaction and main-effect tests simulated here.

On the other hand, if sample sizes are small and unequal, and large samples are associated with the largest population CVs, these score tests can perform poorly. In this
case, the likelihood-ratio tests using $M$ and $D$ are preferred. Practically, however, this situation can be avoided by insuring that all sample sizes exceed 20.

For one-factor experiments, if the sample sizes are equal, the score tests using $\mathbf{M}$ and $D$ are preferred since they preserve the Type I error rate and have higher power than DDT and GM for very small samples. These tests also are generally better when sample sizes are unequal, though DDT and GM are best in some cases.

If data are suspected of belonging to right-skewed distributions in a factorial experiment, but the population CVs are within the range $(0,1 / 3)$ for "ratio-normal" data, the same recommendations given above apply. If the population CVs are outside this range, however, the likelihood-ratio test using IM is generally preferred. In this case, based on simulation results, the score tests are not recommended.

## CHAPTER SIX

## APPLIED EXAMPLES

In this chapter, two applied examples of factorial experiments are introduced and the appropriate models are fitted. The first example is a component of a data set originally discussed by Gerig and Sen (1980) involving relative variability of duck kills in Canadian provinces for the years 1969 and 1970. Gupta and Ma (1996) utilizes one-factor tests for each province to test for a difference in years. With the new method, a global test for interaction between province and year is available. The second example is based on two data sets given in Ott (1993) where the pH level of drug vials stored at two temperatures in two different labs is the variable of interest.

Applied Example \#1

During each of the years 1969 and 1970, as part of the Canada migratory game bird surveys, random samples of hunters were drawn from each Canadian province using lists of the previous year's permit holders. Among hunters reporting at least one duck kill (excluding sea ducks), the $\log$ (base 10 ) of the number of kills per hunter was recorded. Although the log transformation compromises the ratio-level nature of the data, it was claimed by Gerig and Sen (1980) to be necessary in order to induce normality. The observed sample means, standard deviations, and CVs for the four westernmost provinces
are given in Table $X$. Although the data are no longer of the ratio type, they are strictly non-negative. As a result, judging from the observed CV values, the assumption of normality is questionable.

Gupta and Ma (1996) uses a variety of one-factor tests to assess the hypothesis claimed by Gerig and Sen (1980) that the relative variability of log-duck-kills per hunter for 1969 and 1970 were equal for each province. However, no global test of interaction between province and year was available.

For simplicity, only the four westernmost provinces were reanalyzed using a $2 \times 4$ factorial model. The saturated model has the form

$$
\mathbf{R}_{\mathrm{ij}}=\exp \left(\mathbf{R}^{*}+\alpha_{\mathrm{i}}+\beta_{\mathrm{j}}+(\alpha \beta)_{\mathrm{ij}}\right), \mathbf{i}=1,2, \mathbf{j}=1,2,3,4,
$$

where $\exp \left(\mathbf{R}^{*}\right)$ is the overall population $C V, \exp \left(\alpha_{i}\right)$ is the effect of the $i^{\text {th }}$ year, $\exp \left(\beta_{j}\right)$ is the effect of the $\mathrm{j}^{\text {th }}$ province, and the terms $(\alpha \beta)_{\mathrm{ij}}$ describe the interaction between year and province. The identifiability constraint $\sum_{\mathrm{i}=1}^{2} \alpha_{\mathrm{i}}=\sum_{\mathrm{j}=1}^{4} \beta_{\mathrm{j}}=\sum_{\mathrm{i}=1}^{2}(\alpha \beta)_{\mathrm{ij}}=\sum_{\mathrm{j}=1}^{4}(\alpha \beta)_{\mathrm{ij}}=0$ was used. In matrix form, the resulting generalized linear model is given by

$$
\left[\begin{array}{l}
\log \mathrm{R}_{11} \\
\log \mathrm{R}_{12} \\
\log \mathrm{R}_{13} \\
\log \mathrm{R}_{14} \\
\log \mathrm{R}_{21} \\
\log \mathrm{R}_{22} \\
\log \mathrm{R}_{23} \\
\log \mathrm{R}_{24}
\end{array}\right]=\left[\begin{array}{cccccccc}
1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 \\
1 & 1 & 0 & 1 & 0 & 0 & 1 & 0 \\
1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\
1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 \\
1 & -1 & 1 & 0 & 0 & -1 & 0 & 0 \\
1 & -1 & 0 & 1 & 0 & 0 & -1 & 0 \\
1 & -1 & 0 & 0 & 1 & 0 & 0 & -1 \\
1 & -1 & -1 & -1 & -1 & 1 & 1 & 1
\end{array}\right] \quad\left[\begin{array}{l}
\mathrm{R}^{*} \\
\alpha_{1} \\
\beta_{1} \\
\beta_{2} \\
\beta_{3} \\
(\alpha \beta)_{11} \\
(\alpha \beta)_{12} \\
(\alpha \beta)_{13}
\end{array}\right] .
$$

For brevity, only Iglewicz and Myers' approximation was applied to fit the saturated model. The resulting tests of significance of the interaction, based on three degrees of freedom, are appended to Table XI. All tests were clearly significant at the 0.05 level,

TABLE X
OBSERVED MEANS, STANDARD DEVIATIONS, AND CVs OF LOG-DUCK-KILLS (BASE 10) PER HUNTER BY PROVINCE AND YEAR

| Province | Year | n | $\overline{\mathbf{x}}$ | s | r |
| :--- | :---: | :---: | :---: | :---: | :---: |
| British Columbia | 1969 | 503 | 0.9299 | 0.4680 | 0.5034 |
|  | 1970 | 743 | 0.9539 | 0.4906 | 0.5143 |
| Alberta | 1969 | 654 | 1.0817 | 0.4350 | 0.4021 |

## TABLE XI

ESTIMATED PARAMETERS FOR SATURATED MODEL OF CVs OF LOG-DUCK-KILLS (BASE 10) PER HUNTER

| Parameter | Estimate | Standard Error | Effect |
| :---: | :---: | :---: | :--- |
| $\mathbf{R}^{*}$ | -0.8271 | 0.01049 | log overall CV |
| $\alpha_{1}$ | -0.000615 | 0.01049 | 1969 |
| $\beta_{1}$ | 0.1514 | 0.02064 | British Columbia |
| $\beta_{2}$ | -0.03496 | 0.01831 | Alberta |
| $\beta_{3}$ | -0.1089 | 0.01699 | Saskatchewan |
| $(\alpha \beta)_{11}$ | -0.01010 | 0.02064 | $1969 /$ B.C. |
| $(\alpha \beta)_{12}$ | -0.04838 | 0.01831 | $1969 /$ Alberta |
| $(\alpha \beta)_{13}$ | 0.03172 | 0.01699 | $1969 /$ Sask. |

Tests for Interaction: Wald $\chi^{2}: 10.152, \mathrm{p}=0.0173 ;$ LR $\chi^{2}: 10.089, \mathrm{p}=0.0178$; Score $\chi^{2}: 9.626, p=0.0220$, each based on 3 df .
suggesting that the ratio of the relative variabilities of log-duck-kills per hunter (1969 to 1970) was not consistent across provinces. Estimated parameters for the saturated model are given in Table XI. Asymptotic $95 \%$ confidence intervals for the log-ratio and ratio of population CVs (1969 to 1970) for each province are given in Table XII. Apparently, the relative variability of log-duck kills per hunter for Alberta was only between 0.83 and 0.99 times as large in 1969 as in 1970. No significant difference was found for the other provinces.

To demonstrate the versatility of the current modelling technique, the relative variability of the western provinces (British Columbia and Alberta) was contrasted with that of the central provinces (Saskatchewan and Manitoba) for each year. For the multiplicative model, these contrasts estimate the ratio of the geometric average of the "western" population CVs to the geometric average of the "central" population CVs.

Because a normal population CV is a ratio of distinct parameters, a geometric average of two or more CVs preserves information about the contributing means and standard deviations that is typically lost by taking an arithmetic average. This suggests that the multiplicative model should generally be used even in the one-factor case.

For 1969 , the contrast has the form

$$
\begin{aligned}
\log \left(\frac{\left(\mathbf{R}_{11} \mathbf{R}_{12}\right)^{1 / 2}}{\left(\mathbf{R}_{13} \mathbf{R}_{14}\right)^{1 / 2}}\right) & =\frac{1}{2} \log \mathbf{R}_{11}+\frac{1}{2} \log \mathbf{R}_{12}-\frac{1}{2} \log \mathbf{R}_{13}-\frac{1}{2} \log \mathbf{R}_{14} \\
& =\beta_{1}+\beta_{2}+(\alpha \beta)_{11}+(\alpha \beta)_{12}
\end{aligned}
$$

The estimated log-ratio and ratio are 0.05799 and 1.0597 , respectively, and the corresponding asymptotic $95 \%$ confidence intervals are $(-0.002843,0.1188)$ and ( 0.9972 ,

## TABLE XII

## ASYMPTOTIC 95\% CONFIDENCE INTERVALS FOR LOG-RATIO AND RATIO OF CVs OF LOG-DUCK-KILLS (BASE 10) PER HUNTER (1969 TO 1970) BY PROVINCE

| Log-Ratio | CI | Estimate | Ratio |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Estimate |  |  |  |
| B. C. | -0.02142 | $(-0.1199,0.07710)$ | 0.9788 | $(0.8870,1.0802)$ |
| Alberta | -0.09800 | $(-0.1812,-0.01480)$ | 0.9067 | $(0.8343,0.9853)$ |
| Sask. | 0.06220 | $(-0.01189,0.1363)$ | 1.0642 | $(0.9882,1.1460)$ |
| Manitoba | 0.05230 | $(-0.01816,0.1228)$ | 1.0537 | $(0.9820,1.1306)$ |

1.1262). For 1970, the estimated log-ratio and ratio are 0.1750 and 1.1912 , with asymptotic $95 \%$ confidence intervals $(0.1204,0.2295)$ and $(1.1279,1.2580)$.

It would appear that the relative variability of the western provinces was
significantly higher than that of the central provinces in 1970 but not in 1969 , which helps to explain the significant interaction.

## Applied Example \#2

Ott (1993, pp. 916, 919) lists the observed pH levels of 2-mL vials of a drug product stored at each of two temperatures $\left(30^{\circ} \mathrm{C}\right.$ and $\left.40^{\circ} \mathrm{C}\right)$ in two labs (\#1 and \#2). Twelve vials were examined from each temperature-lab combination. The data, along with the sample means, standard deviations, CVs, and Shapiro-Wilk statistics for testing normality (SAS Institute, Inc., 1990, p. 627) are given in Table XII. The objective in this applied example is to estimate a factorial model that describes how each factor influences the relative variability of the pH .

Technically, pH is not a ratio-level variable, partly because a negative pH is possible, and partly because the pH is computed as a (negative) $\log$ (base 10) of hydrogen ion concentration in a solution (Holtzclaw and Robinson, 1988, pp. 479-480). However, it represents a variable whose relative consistency is potentially of interest and so is considered here.

The saturated model has the form

$$
\mathbf{R}_{\mathrm{ij}}=\exp \left(\mathbf{R}^{*}+\alpha_{\mathrm{i}}+\beta_{\mathrm{j}}+(\alpha \beta)_{\mathrm{ij}}\right), \mathbf{i}=1,2, \mathbf{j}=1,2
$$

where $\exp \left(R^{*}\right)$ is the overall population $C V, \exp \left(\alpha_{i}\right)$ is the effect of the $i^{\text {th }}$ temperature, $\exp \left(\beta_{\mathrm{j}}\right)$ is the effect of the $\mathrm{j}^{\text {th }}$ lab, and the terms $\exp \left((\alpha \beta)_{\mathrm{ij}}\right)$ describe the interaction

TABLE XIII
OBSERVED MEANS, STANDARD DEVIATIONS, AND CVs OF pH LEVELS BY TEMPERATURE AND LAB

| Temperature Lab | pH Data | $\overline{\mathbf{x}}$ | $\mathrm{S}_{\mathrm{n}}$ | $\mathrm{r}_{\mathrm{n}}$ |
| :---: | :---: | :---: | :---: | :---: |
| $30^{\circ} \mathrm{C}$ \#1 | 3.45, 3.48, 3.50, 3.55 | 3.5883 | 0.09754 | 0.02718 |
| $(\mathrm{W}=0.905, \mathrm{p}=0.173)$ | 3.56, 3.57, 3.59, 3.60 |  |  |  |
|  | 3.60, 3.61, 3.74, 3.81 |  |  |  |
| $\begin{array}{cc} 30^{\circ} \mathrm{C} & \# 2 \\ (\mathrm{~W}=0.921, \mathrm{p}=0.277) \end{array}$ | 3.70, 3.74, 3.75, 3.76 | 3.8108 | 0.06689 | 0.01755 |
|  | 3.77, 3.80, 3.80, 3.84 |  |  |  |
|  | $3.87,3.90,3.90,3.90$ |  |  |  |
| $\begin{array}{cc} 40^{\circ} \mathrm{C} & \# 1 \\ (\mathrm{~W}=0.931, \mathrm{p}=0.367) \end{array}$ | 3.29, 3.32, 3.38, 3.39 | 3.5108 | 0.1348 | 0.03838 |
|  | 3.45, 3.51, 3.59, 3.60 |  |  |  |
|  | 3.61, 3.63, 3.65, 3.71 |  |  |  |
| $\begin{array}{cc} 40^{\circ} \mathrm{C} & \# 2 \\ (\mathrm{~W}=0.906, \mathrm{p}=0.179) \end{array}$ | 3.60, 3.64, 3.68, 3.70 | 3.7233 | 0.06587 | 0.01769 |
|  | $3.70,3.70,3.70,3.75$ |  |  |  |
|  | $3.80,3.80,3.80,3.81$ |  |  |  |

Values given in parentheses are the Shapiro-Wilk statistics and p-values for testing the null hypotheses that the samples were drawn from normal distributions.
between temperature and lab. The identifiability constraint $\sum_{i=1}^{2} \alpha_{i}=\sum_{j=1}^{2} \beta_{j}=\sum_{i=1}^{2}(\alpha \beta)_{i j}=$ $\sum_{\mathrm{j}=1}^{2}(\alpha \beta)_{\mathrm{ij}}=0$ was used. In matrix form, the resulting generalized linear model is given by

$$
\left[\begin{array}{l}
\log \mathrm{R}_{11} \\
\log \mathrm{R}_{12} \\
\log \mathrm{R}_{21} \\
\log \mathrm{R}_{22}
\end{array}\right]=\left[\begin{array}{cccc}
1 & 1 & 1 & 1 \\
1 & 1 & -1 & -1 \\
1 & -1 & 1 & -1 \\
1 & -1 & -1 & 1
\end{array}\right]\left[\begin{array}{l}
\mathrm{R}^{*} \\
\alpha_{1} \\
\beta_{1} \\
(\alpha \beta)_{11}
\end{array}\right]
$$

McKay's approximation was applied to fit the model. The corresponding tests for interaction, based on one degree of freedom, are appended to Table XIV. Note that there is clearly no evidence of interaction, so that a reduced model with only main effects was considered.

In order to determine if both main effects are significant, Wald tests were conducted on the estimated parameters of the main-effects model, while each main effect was individually removed in turn so that associated likelihood-ratio and score tests also could be constructed. These conditional $\chi^{2}$ statistics for assessing the significance of temperature and lab, each based on one degree of freedom, also are appended to Table XIV.

Apparently, temperature can be removed from the model. The estimated parameters of the resulting "lab" model are given in Table XIV. Updated tests for the significance of the lab effect also are included. To assess the overall adequacy of this model, a global test for interaction and temperature effects also was conducted which corroborated these findings (Wald $\chi^{2}: 1.307, p=0.520 ;$ LR $\chi^{2}: 1.282, p=0.527 ;$ Score $\chi^{2}: 1.210, p=0.546$, each based on 2 df$)$.

TABLE XIV
ESTIMATED PARAMETERS FOR LAB MODEL OF CVs OF pH LEVELS

| Parameter | Estimate | Standard Error | Effect |
| :--- | :---: | :---: | :--- |
|  |  |  |  |
| $\mathbf{R}^{*}$ | -3.6775 | 0.1067 | $\log$ overall CV |
| $\beta_{1}$ | 0.3175 | 0.1067 | Lab \#1 |

Tests for Interaction: Wald $\chi^{2}: 0.624, p=0.429 ;$ LR $\chi^{2}: 0.621, p=0.431$;
Score $\chi^{2}: 0.613, p=0.434$, each based on 1 df .
Tests for Temperature $\backslash \mathrm{Lab}:$ Wald $\chi^{2}: 0.683, p=0.409 ; \operatorname{LR} \chi^{2}: 0.661, p=0.416$;
Score $\chi^{2}: 0.633, p=0.426$, each based on 1 df .
Tests for Lab | Temperature: Wald $\chi^{2}: 8.065, p=0.005 ; \operatorname{LR} \chi^{2}: 7.437, p=0.006$;
Score $\chi^{2}: 6.185, p=0.013$, each based on 1 df .
Tests for Lab Only: Wald $\chi^{2}: 8.859, p=0.003 ; \operatorname{LR} \chi^{2}: 8.323, p=0.004 ;$
Score $\chi^{2}: 6.930, p=0.008$, each based on 1 df .

Based on the fitted 'lab" model, the estimated log-ratio and ratio for lab (\#1 to \#2), irrespective of storage temperature, are 0.6350 and 1.8871 , respectively, while the asymptotic $95 \%$ confidence intervals are $(0.2168,1.0532)$ and $(1.2421,2.8668)$. It appears that vials stored in lab \#1 have a significantly higher relative variability than those stored in lab \#2.

## CHAPTER SEVEN

## CONCLUSION

The modelling approach developed in this thesis is significant because it expands the settings in which the normal population CV may be analyzed to include designed factorial experiments. In particular, the use of approximations of the distribution of the sample CV provides a context well suited to the application of the generalized linear model and its iterative algorithms for model estimation. When the CV is the population characteristic of interest, the approach is apparently superior to the modelling efforts associated with Taguchi because it incorporates estimable model and covariance structures for the observed sample CVs rather than use transformed CVs that are assumed to have constant variance. As a result, estimated model parameters are easily interpreted, tests of all effects in a fitted factorial model are available, and asymptotic confidence intervals for ratios of contrasted population CVs are readily obtained. Further, the approach incorporates several tests for the equality of population CVs in a one-factor experiment which have previously been discussed in the literature.

Several related topics are available for future research. Of principal importance is a detailed investigation of the behavior of the exact and approximate likelihood surfaces under consideration in the context of the score test. Evidently, in both factorial and onefactor experiments, when larger samples are associated with populations having larger CV
values, and the overall sample sizes are small, the likelihood surfaces are poorly behaved, since the powers of the associated score tests are very low. The existence of a unique maximum is apparently not an issue, but rather the behavior of the surfaces at points other than the maximum.

The current modelling approach is based on approximate distributions because the structure of these distributions is simple and easily incorporated into the theory of generalized linear models. However, an exact model of the population CV also could be obtained using the normal likelihood of the observed data reparameterized in terms of the $\mathrm{R}_{\mathrm{i}}$ and $\mu_{\mathrm{i}}$ as in Gupta and Ma (1996). In this case, model (4.1) and a corresponding multiplicative model of the $\mu_{\mathrm{i}}$ could be estimated via maximum-likelihood and compared to the current models, although a direct application of the Fisher scoring algorithm without the benefit of generalized linear models would be necessary.

Rather than estimate the variances of the observed sample CVs in the context of a generalized linear model, the observed data might also be resampled via a bootstrap or jackknife technique to obtain estimated variances which could be incorporated into a weighted least squares model. For example, if a multiplicative model of the $\mathbf{R}_{i}$ is desired, then (4.5) might be estimated as an additive model using the $\log r_{i}$ as the responses, with weights obtained by estimating the variances of the $\log r_{i}$ using a resampling scheme. Estimated model parameters could be tested using a Wald procedure and reduced models could be fitted using the resampled variance estimates as weights. Presumably, resulting parameter estimates would at least be comparable to those obtained via generalized linear models and better than those obtained using the Taguchi approach.

Lastly, the likelihood-ratio test using Iglewicz and Myers' approximation often has the best power as a test of an effect in a factorial or one-factor experiment. However, its Type I error rate is extremely poor, especially for small samples. As a result, Bartlett's correction factor could likely be used to improve the $\chi^{2}$ approximation for this test when sample sizes are small (Shafer and Sullivan, 1986), although its effect on power would need to be investigated.

## APPENDIX B

## SAS PROGRAM TO CALCULATE EXACT AND APPROXIMATE QUANTILES

This SAS program generates selected quantiles from the exact distribution of the sample CV for data drawn from a normal population using the method of Owen (1968). Corresponding quantiles from McKay's, David's, and Iglewicz and Myers' approximations are also calculated.
********************************************************/

## APPENDIX C

## SAS PROGRAM TO SIMULATE

 THE INTERACTION TESTThis SAS program simulates the test of interaction using data from normal populations arranged in a $2 \times 2$ factorial having CVs determined by the model

$$
\mathbf{R}=\exp (\text { rstar }+\mathbf{a}+\mathbf{b}+\mathbf{a b})
$$

where $\exp (r s t a r)$ is the overall population $C V, \exp (a)$ is the effect of factor $A, \exp (b)$ is the effect of factor $B$, and $\exp (a b)$ is the effect of interaction between A and B. For simplicity, both main effects in the generating model are set to zero.
******************************************************/

\section*{APPENDIX D}

\section*{SAS PROGRAM TO SIMULATE THE MAIN-EFFECT TEST}

This SAS program simulates the test of a main effect using data from normal populations arranged in a \(2 \times 2\) factorial having CVs determined by the model
\[
\mathbf{R}=\exp (\text { rstar }+\mathbf{a}+\mathbf{b})
\]
where \(\exp\) (rstar) is the overall population CV, \(\exp (a)\) is the effect of factor \(A\), and \(\exp (b)\) is the effect of factor B. In order to examine the capability of the tests in a proper setting, no interaction is included in the generating model. For simplicity, one main effect, say A, is also set to zero in the generating model.

Craig Alan Wilson
Candidate for the Degree of
Doctor of Philosophy

## Thesis: AN APPROACH TO MODELLING THE COEFFICIENT OF VARIATION IN FACTORIAL EXPERIMENTS

Major Field: Statistics
Biographical:
Personal Data: Born in Russellville, Arkansas on October 15, 1970, the son of Delbert and Sharon Wilson.

Education: Graduated from Central High School, Tulsa, Oklahoma in June 1988; received Associate in Science degree in Mathematics from Tulsa Community College, Tulsa, Oklahoma in July 1990; received Bachelor of Science degree in Mathematics from Oklahoma State University, Stillwater, Oklahoma in May 1992; received Master of Science degree in Statistics from Oklahoma State University, Stillwater, Oklahoma in December 1994. Completed the requirements for the Doctor of Philosophy degree with a major in Statistics at Oklahoma State University in May 1998.

Experience: Employed as a graduate teaching associate at Oklahoma State University, Department of Statistics, from 1994 to present; employed as a graduate teaching assistant at Oklahoma State University, Department of Statistics, from 1992 to 1994.

Professional Memberships: American Statistical Association

[^0]:    IM = Iglewicz and Myers' Approximation
