**A COMPARISON OF TWO-PHASE
INFLOW PERFORMANCE RELATIONSHIPS**

A THESIS

**APPROVED FOR THE SCHOOL OF PETROLEUM
AND GEOLOGICAL ENGINEERING**

BY

ACKNOWLEDGMENTS

I would like to express my profound gratitude to Dr. Michael E. Wright, who served as the major professor for this thesis. Without his guidance, this study would not be brought to an end. Thanks are also extended to Dr. Ronald Evans and Dr. Samuel Osisanya for serving as members of the committee. The financial support provided by the School of Petroleum and Chemical Engineering has made my graduate studies possible and I gratefully acknowledge this support. Finally, I would like to thank all my family, and in particular my parents for their patience, understanding and support during the last two years.

For these reasons, I wish to dedicate this thesis to people mentioned and to the others who helped me throughout this journey.

ACKNOWLEDGMENTS

I would like to express my profound gratitude to Dr. Michael L. Wiggins, who served as the major professor for this thesis. Without his guidance, this study could not be brought to an end. Thanks are also extended to Dr. Ronald Evans and Dr. Samuel Osisanya for serving as members of the committee. The financial support provided by the School of Petroleum and Geological Engineering has made my graduate studies possible and I gratefully acknowledge that support. Finally, I would like to thank all my family, and in particular my parents for their patience, understanding and support during the last two years.

For these reasons, I wish to dedicate this thesis to the people mentioned and to the others who helped me throughout this startling time in United States

The objective of this study is to predict the rate-pressure behavior of gas reservoirs.

Inflow performance curves were predicted for 15 wells based on actual field data. The predicted rates were compared to actual measured gas well pressure data. The variation between the predicted and actual rates for the various wells studied has been analyzed.

Based on this analysis, it is recommended that the most reliable method for predicting gas well inflow performance curves is the most consistent method. In addition, it was observed that the new method provided the best results for all cases and it is recommended that studies be conducted to evaluate the potential pressure behavior of gas wells.

ABSTRACT

In this research, the individual performance of vertical oil wells are investigated. The objective of this study was to verify the suitability of certain empirical relations to predict the rate-pressure behavior of a single oil well producing from solution-gas drive reservoirs.

Inflow performance curves were generated for 26 cases based on actual field data. The predicted rates were then compared to actual measured rate and pressure data. The variation between the measured and predicted rates by the various methods studied has been analyzed.

Based on this analysis, multipoint performance methods generally provide the most reliable estimates of well performance. Fetkovich's multipoint method was the most consistent performance prediction for the cases studied. In addition, it was observed that no one method presented the best results for all cases and it is recommended that multipoint performance methods be utilized to yield a range of potential pressure-production behavior.

CHAPTER 1

INTRODUCTION

Reservoirs are investigated for exploration around the world. As the reserves of oil or gas are produced, petroleum companies are exploring places which are increasingly difficult and costly to access. If companies want to develop a venture in such areas, it must make sure the potential of such a reservoir would at least cover the investment needed for the enterprise. Millions of dollars are at stake, so a slight misvaluation could result in a catastrophic venture.

For this reason it is important to estimate a well's deliverability at the beginning of field development. Consequently, an important role of the petroleum engineer is to predict the performance of individual wells. Estimates of well performance allows the engineer to evaluate various operating conditions and determine the optimum production scheme and design production and artificial lift equipment when necessary. They can also be used to design and evaluate the effects of stimulation treatments. In addition, estimates of future performance can be made from this information for forecasting and planning purposes. It is therefore of important to estimate the pressure-production behavior of a well. This thesis will review and compare various methods that have been proposed in the literature for describing individual well performance in solution-gas drive reservoirs.

1.1 Research Objectives

During the past sixty years, a number of relations have been proposed for the

prediction of well performance at present and future time. Some are based on simulator results which were used to develop relationships while others were developed from field observations. Each method has advantages, disadvantages and limitations. The objectives of this research are to: (1) review well performance prediction methods, (2) apply these methods using field data, and, (3) evaluate and compare the methods.

The objectives would be readily achieved if one could obtain actual well data as easy as changing parameters during computer simulation runs. However, this is not the case and for this study to be meaningful, field data had to be obtained. The data utilized has been reported in the petroleum engineering literature and will be used in this analysis. While the data may appear limited, it covers a range of solution-gas drive reservoirs where the reservoir pressure is below its bubble point pressure. This data will provide a qualitative evaluation of the various well performance methods reviewed in this study.

1.2 Background

The productivity of a well should be an indication or measure of the producing rate of the reservoir within the drainage radius of the well. The methods of measuring productivity are many and varied depending on the operator and type of well. The method most commonly used at the beginning of this century was the open-flow potential through the casing. This method gradually lost favor, as it was wasteful, expensive, and, frequently, quite detrimental to the well and reservoir. Open-flow tests were not a true indicator of the comparative ability of the formation to yield oil, due to the wide variance in equipment, such as casing size, wellhead, separators, etc. While

using this technique operators felt compelled to complete the well with equipment so that it was assured the maximum potential was reached, which increased well costs. In addition, the high rate of production during open-flow potential tests greatly reduced the bottomhole pressure, often causing formation damage and premature water encroachment which resulted in lower recovery of oil and higher lifting costs.¹

Petroleum engineers were aware of this, and in the 1920's, the use of a restricted potential became popular throughout the industry. The restricted potential could be taken through the casing using a uniform size choke at the casinghead. A relationship would be established between the open-flow and tubing potentials with the open-flow potential determined indirectly thereafter from the use of the tubing potential. Tubing potential was an improvement over open-flow potential but still had the disadvantage of comparing well-to-well derivability due to the inability of each well to demonstrate its full capacity. This was indicated by the fact that a large proportion of wells show approximately the same potential although differences in their flowing pressures indicated the ability of some to produce was greater than others.¹

In 1930, Moore¹ suggested a new method of determining the relative productivity of a well without an open-flow test. This method involved the measurement of the static bottomhole pressure and the flowing bottomhole pressure at various rates of production. This measure of the ability of a well to produce was termed its productivity index (PI), which is the ratio of the production rate to the differential between the static and flowing bottomhole pressures

$$J = \frac{q}{P_r - P_{wf}} \quad (1)$$

As shown in Eq. 1, the PI is an indication of the ability of the reservoir to produce formation fluids to the wellbore as it does not take into account the resistance of the flow string, but measures only the resistance of flow through the porous media.

The PI can be developed from Darcy's relationship for single-phase, incompressible flow and relates the rate-pressure function to reservoir parameters

$$J = \frac{q_o}{p_r - p_{wf}} = \frac{2\pi hk}{B_o \mu_o (\ln(r_e / r_w) - 0.5)} \quad (2)$$

In 1936 Rawlins and Schellhardt² proposed an empirical relation to estimate deliverability for gas wells based on multirate test data. Their relationship was

$$q_g = C(p_r^2 - p_{wf}^2)^n \quad (3)$$

The relationship was developed after interpreting several hundred multirate gas well tests. A linear trend was observed on a log-log plot of flow rate versus the difference in the squares of the reservoir pressure and the flowing wellbore pressure. Extrapolation of this line enabled the maximum possible flow rate to be estimated from the graph as presented Fig 1.1. This maximum rate was termed the absolute open flow (AOF). In the equation written above, n is the reciprocal of the slope of the line on the log-log plot.

As mentioned earlier, Darcy's relation is applicable for single-phase flow. In 1942 Evinger and Muskat³ pointed out that a straight line PI should not be valid when

multiphase flow occurs in the reservoir. Multiphase flow can result when the reservoir pressure or the flowing bottomhole pressure is below the bubble point pressure of the oil resulting in liquid and vapor flowing in the reservoir. Most oil wells will produce under multiphase flow conditions for part, if not the majority, of their productive lives. They presented theoretical results which led to the conclusion that the relationship between flow rate and pressure has a curved shape rather than a straight line when two phases are flowing. Their relationship is

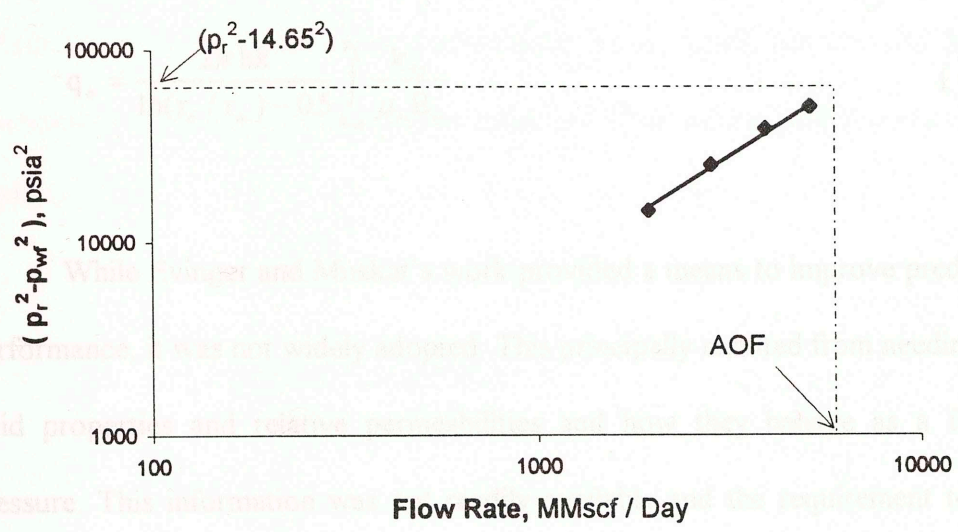

Fig. 1.1- Back-pressure curve for a gas well.

1.3 Two-phase flows

The birth of the computer industry opened a new horizon for petroleum engineers. Since then, the size and capacity of computers have been repeatedly reduced and augmented by orders of magnitude. The petroleum engineer quickly embraced the technology, and as soon as 1960 some pioneers in computer

multiphase flow occurs in the reservoir. Multiphase flow can result when the reservoir pressure or the flowing bottomhole pressure is below the bubble point pressure of the oil resulting in liquid and vapor flowing in the reservoir. Most oil wells will produce under multiphase flow conditions for part, if not the majority, of their producing lives. They presented theoretical results which lead to the conclusion that the relationship between flow rate and pressure has a curved shape rather than a straight line when two phases are flowing. Their relationship is:

$$q_o = \frac{2\pi hk}{\ln(r_e / r_w) - 0.5} \int_{p_{wf}}^{p_r} \frac{k_{ro}}{\mu_o B_o} \quad (4)$$

While Evinger and Muskat's work provided a means to improve predicting well performance, it was not widely adopted. This principally resulted from needing to know fluid properties and relative permeabilities and how they behave as a function of pressure. This information was not readily available and the requirement to integrate the relationship made it difficult for the petroleum engineer to implement in a ready manner.

1.3 Two-phase IPRs

The birth of the computer industry opened a new horizon for petroleum engineers. Since then, the size and capacity of computers have been respectively reduced and augmented by orders of magnitude. The petroleum engineer quickly embraced the technology, and as soon as 1960 some pioneers in computer

programming like Weller⁴ developed programs and numerical solutions from which they computed the saturation and pressure profile within the reservoir.

Vogel⁵, in 1968, was able to generate an empirical relation for solution-gas drive reservoir based on simulation results using Weller's algorithm. Vogel noticed that the shape of the pressure-rate curves for a wide range of rock and fluid properties were very similar. He had the brilliant idea to make the plot dimensionless, and observed the individual curves collapsed to a small band (Fig. 1.2). Vogel divided the pressure at each point by the reservoir pressure and the flow rate by the maximum flow rate to obtain the dimensionless inflow performance curve. Using his data he developed a relationship to describe the observed behavior. This inflow performance relationship (IPR) is

$$\frac{q_o}{q_{o \max}} = 1 - 0.2 \left(\frac{p_{wf}}{p_r} \right) - 0.8 \left(\frac{p_{wf}}{p_r} \right)^2 \quad (5)$$

Vogel's IPR obtained almost immediate acceptance by the petroleum industry due to the ease of use and the minimal test information needed. The most important limitation of his contribution was that field verification was missing. However, his relation is commonly used in the industry today which demonstrates its applicability in the field.

By comparing the performance curves of liquid, gas, and two-phase flow shown in Fig 1.3, Fetkovich⁶ observed the two-phase curve was closer to the gas curve rather

Fig 1.2 - Vogel's Dimensionless Inflow Performance

Relationship (from Ref. 5).

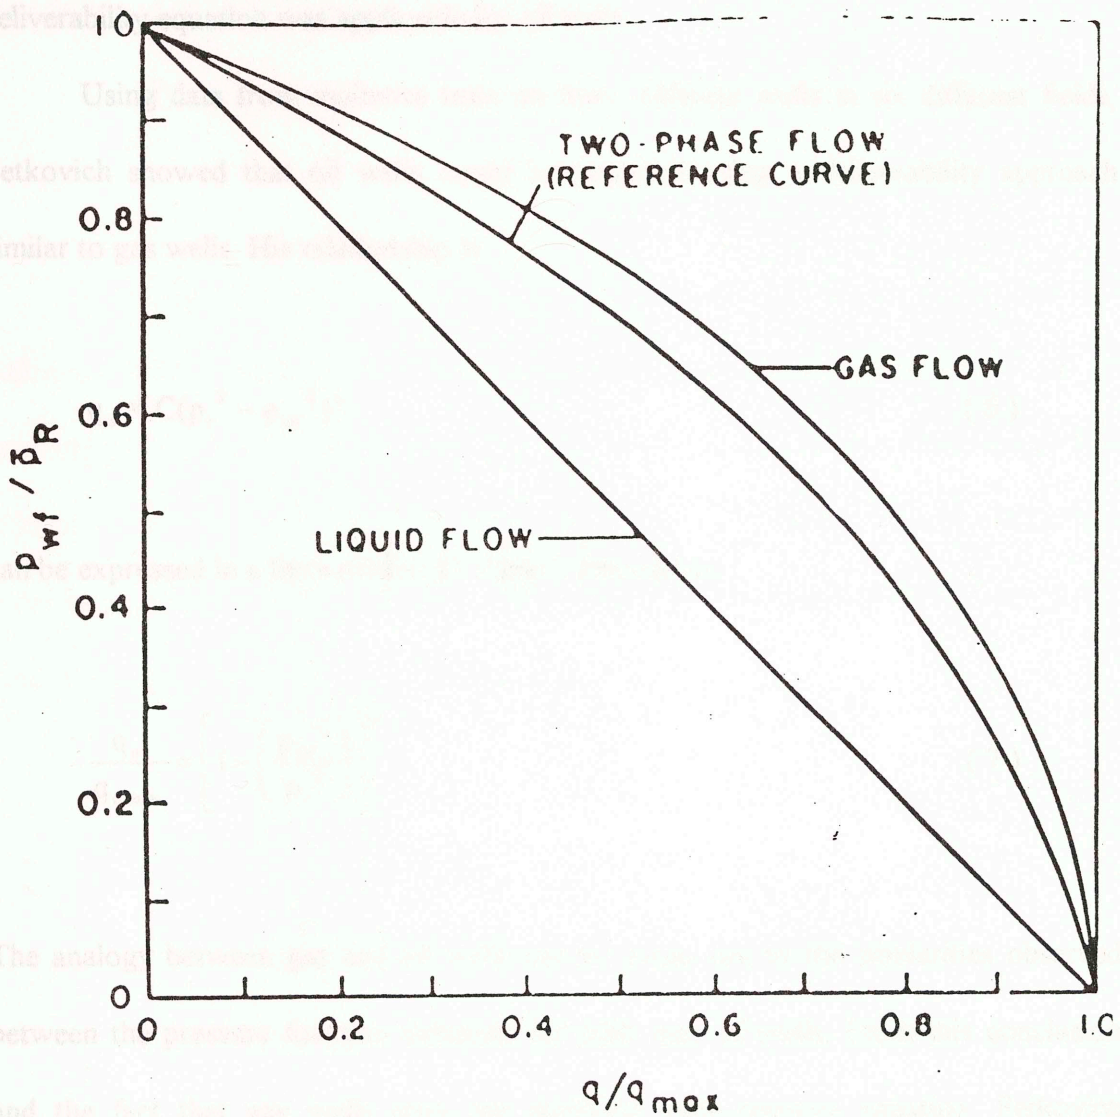

Fig. 1.3 - Comparison of IPRs for liquid, gas and two-phase flow (from Ref. 5).

than to the liquid curve. From this, he proposed Rawlins and Schellhardt's gas well deliverability equation was applicable for oil wells.

Using data from multirate tests on forty different wells in six different fields, Fetkovich showed that oil wells could be analyzed using a deliverability approach similar to gas wells. His relationship is

$$q_o = C(p_r^2 - p_{wf}^2)^n \quad (6)$$

can be expressed in a form similar to Vogel's relation as:

$$\frac{q_o}{q_{o\max}} = \left[1 - \left(\frac{p_{wf}^2}{p_r^2} \right) \right]^n \quad (7)$$

The analogy between gas and oil wells can be made due to the similarities observed between the pressure function behavior for both type of wells. From this conclusion and the fact that gas wells obey the empirical back-pressure equation, Fetkovich suspected and proved that it should be the same for oil wells.

Fetkovich's field verifications provided solid support for his IPR method and it was quickly accepted in the industry. His method, unfortunately, requires a multipoint test to be able to determine the exponent n . To overcome this limitation, his method has been modified to assume n is equal to unity when multipoint test data are unavailable.

completion effectiveness. Using Forchheimer's⁸ model to describe non-Darcy flow, they proposed the following relationship between pressure and rate.

$$\frac{p_r - p_{wf}}{q_o} = C + Dq_o \quad (8)$$

From this equation it is evident that a cartesian plot of the ratio of the pressure difference to flow rate versus the flow rate yields a straight line with a slope D and an intercept C . The term C in the equation is called the laminar flow coefficient, and D is referred to as the turbulence coefficient. This approach requires a multipoint test in order to determine C and D . Once these two terms are estimated, the flow rate at any other flowing pressure can be determined from

$$q_o = \frac{-C + \sqrt{C^2 + 4D(p_r - p_{wf})}}{2D} \quad (9)$$

A major contribution of this work is the ability to evaluate completion effectiveness based on the turbulence coefficient, D . The authors presented relations for C and D which can be compared to values from the test data, these relations are

$$C = \frac{\mu B_o}{1.127E - 3(2\pi kh)} \left\{ \ln \left(0.47 \frac{r_e}{r_w} \right) + S \right\} \quad (10)$$

and

and

$$D = \frac{(9.08E - 13)\beta B_o^2 \rho}{4\pi^2 h^2 r_w} \quad (11)$$

By knowing D for a certain set of completion parameters, one can determine D after a change. For example, it can be used to evaluate the effect of flow through a gravel pack or along a fracture or a change in perforation density. It is important from a production standpoint to know the effectiveness of the well completion. A series of very short tests may be sufficient for this purpose where otherwise a long term build-up test may be required. Thus, knowing the laminar and turbulence coefficients may help for the purpose of enhancing the productivity of a well.

Based on Vogel's work, Klins and Majcher⁹ developed a new inflow performance relationship incorporating the bubble point pressure. The authors used a computer simulation program and simulated twenty-one wells which lead to 1,344 IPR curves. Using a non-linear regression package to analyze their data, they presented the following IPR.

$$\frac{q_o}{q_{o\max}} = 1 - 0.295 \left(\frac{p_{wf}}{p_r} \right) - 0.705 \left(\frac{p_{wf}}{p_r} \right)^d \quad (12)$$

where

$$d = \left[0.28 + 0.72 \frac{p_r}{p_b} \right] (1.235 + 0.001 p_b) \quad (13)$$

The proposed equation is not quadratic with respect to pressure but include a new exponent d which is a function of the bubble point pressure.

A limitation of this work is that it is based on a computer simulation study, which is only as good as the assumptions made to build the model. In addition, to utilize the relationship, one needs the estimate value of the bubble point pressure. This pressure is not always available and one would have to rely on correlations to estimate this value.

Sukarno¹⁰ developed an IPR that takes into account for the variation of the flow efficiency when the flowing bottomhole pressure changes. He attempted to describe the flow restriction due to increasing gas saturation around the wellbore as the pressure drawdown increases, the so called rate and time dependent skin, $S(q,t)$. Using a single well, three-phase simulator and a definition of flow efficiency as a ratio of the productivity index at actual conditions to ideal conditions, Sukarno developed by non-linear regression analysis the following formula

$$\frac{(q_o)_{\text{actual}}}{q_{o,\text{max}@S=0}} = \text{FE} \left\{ 1 - 0.1489 \left(\frac{P_{\text{wf}}}{P_r} \right) - 0.4418 \left(\frac{P_{\text{wf}}}{P_r} \right)^2 - 0.4093 \left(\frac{P_{\text{wf}}}{P_r} \right)^3 \right\} \quad (14)$$

where

$$\text{FE} = \left\{ a_0 + a_1 \left(\frac{P_{\text{wf}}}{P_r} \right) + a_2 \left(\frac{P_{\text{wf}}}{P_r} \right)^2 + a_3 \left(\frac{P_{\text{wf}}}{P_r} \right)^3 \right\} \quad (15)$$

and

$$a_n = b_0 + b_1 S + b_2 S^2 + b_3 S^3 \quad (16)$$

Table 1.1 - Constants for Eq. 16

The values of Eq. 16 are given in Table 1.1.

1.4 Future Performance Relationships

In parallel to the development of the IPR, the engineer desires to estimate the pressure-production behavior as the reservoir pressure declines from the test condition. Standing¹¹ was one of the first to look at predicting future performance from an IPR. He defined a new parameter J^* which is a modified PI when the flowing pressure converges to the static pressure. The problem with his method was that reservoir fluid properties needed to be calculated at present and future time. He presented the following relationship to predict the future J_f^*

$$\frac{J_f^*}{J_p^*} = \frac{\left(\frac{k_{ro}}{\mu_o B_o} \right)_f}{\left(\frac{k_{ro}}{\mu_o B_o} \right)_p} \quad (17)$$

where

$$J_p^* = \frac{1.8q_o}{p_r \left(1.0 - 0.2 \left(\frac{p_{wf}}{p_r} \right) - 0.8 \left(\frac{p_{wf}}{p_r} \right)^2 \right)} \quad (18)$$

The difficulties in estimating saturations and relative permeabilities at present and future conditions limits the application of Standing's method in practice.

Fetkovich's constant **Table 1.1 - Constants for Eq. 16**

ratio proposed by Standing could be estimated by a linear relationship of the reservoir pressure ratio. From this idea he proposed an equation to permit the calculation of the future maximum rate. The relation is

	b_0	b_1	b_2	b_3	r^2
a_0	1.03940	0.12657	0.01350	-0.00062	0.9995
a_1	0.01668	-0.00385	0.00217	-0.00010	0.9911
a_2	-0.0858	0.00201	-0.00456	0.00020	0.9958
a_3	0.00952	-0.00391	0.00190	-0.00001	0.9973

what was needed for the inflow performance relation. The major drawback is the assumption that the exponent n and the coefficient C stay the same at the future time.

Ohri and Brown¹⁰ suggested a "pivot point" method based on two flow tests conducted at two different reservoir pressures. From the slopes at the two test points computed using Vogel's relation, one can draw two lines and the intersection point is called the pivot point. The future IPR curves can be predicted by assuming that all lines will intersect at the same point. The method can be used graphically or numerically. Mathematically, the future maximum flow rate can be calculated from the following equations:

$$Q_{max} = \frac{Q_1 Q_2 (P_1 - P_2)}{Q_1 (P_2 - P_1) + Q_2 (P_1 - P_2)} \quad (20)$$

where

Fetkovich⁶ commented on future performance prediction and anticipated the J^* ratio proposed by Standing could be estimated by a linear relationship of the reservoir pressure ratio. From this idea he proposed an equation to permit the calculation of the future maximum rate. The relation is

$$\frac{q_{o,max,f}}{q_{o,max,p}} = \frac{p_{r,f}}{p_{r,p}} \left[\frac{p_{r,f}^2}{p_{r,p}^2} \right]^n \quad (19)$$

The main advantage of his relation is that it does not require any more information than what was needed for the inflow performance relation. The major drawback is the assumption that the exponent n and the coefficient C stay the same at the future time.

Uhri and Blount¹² suggested a “pivot point” method based on two flow tests conducted at two different reservoir pressures. From the slopes at the two end points computed using Vogel’s relation, one can draw two lines and the intersection point is called the pivot point. The future IPR curves can be predicted by assuming that all lines will intersect at the same point. The method can be used graphically or numerically. Mathematically, the future maximum flow rate can be calculated from the following equations.

$$q_{o,max,f} = \frac{Ap_{r,f}^2}{p_{r,f} + n} \quad (20)$$

where

$$A = \frac{p_{r1} - p_{r2}}{\frac{p_{r1}^2}{q_{o,max,1}} - \frac{p_{r2}^2}{q_{o,max,2}}} \quad (21)$$

and

$$n = p_{r1} \left[\frac{A p_{r1}}{q_{o,max,1}} - 1 \right] \quad (22)$$

In 1985 Kelkar and Cox¹³ presented new equations which required two sets of data at two different pressures. Eqs. 23 through 26 present their method where any IPR can be used to determine the maximum flow rate.

$$q_{o,max,f} = A' p_{r,f}^3 + B' p_{r,f} \quad (23)$$

where

$$J^* = \frac{q_{o,max}}{p_r} \quad (24)$$

and

$$A' = \frac{J_1^* - J_2^*}{p_{r1}^2 - p_{r2}^2} \quad (25)$$

and

$$B' = \frac{\frac{J_1^*}{p_{r1}^2} - \frac{J_2^*}{p_{r2}^2}}{\frac{1}{p_{r1}^2} - \frac{1}{p_{r2}^2}} \quad (26)$$

Klins and Clark¹⁴ presented a new method to predict future performance where the bubble point pressure is considered a reference point. From their relations C and n at future time must be computed after the estimation of these parameters at current conditions from Fetkovich's equation. Once these parameters are estimated, the maximum future production rate is calculated by using Fetkovich's equation,

$$q_{o,max,f} = C_f (p_{i,f}^2)^{n_f} \quad (27)$$

where

$$n_f = n_{pb} \left(\frac{n}{n_{pb}} \right)_f \quad (28)$$

and

$$C_f = C_{pb} \left(\frac{C}{C_{pb}} \right)_f \quad (29)$$

To use this method, one needs a multipoint test in order to be able to compute the value of n and C at the test conditions.

1.5 Summary.

The ability to predict the performance of an oil well has always captured the attention of the petroleum engineer. Many relationships have been proposed to assist the engineer in predicting this performance. In this study, we compare the predictions of the various IPRs for two-phase flow to actual field test data. These comparisons are presented and discussed in the following chapters. Chapter 2 discusses the process for implementing the various relationships while Chapter 3 details the comparison to actual

field data. Finally, a summary of this study and its major conclusions are presented in Chapter 4.

INFLOW PERFORMANCE RELATIONSHIPS

The various inflow performance relationships to be evaluated were presented in Chapter 3. This chapter discusses how the relationships are applied by using an example. In addition, a spreadsheet program developed to perform the comparison is described.

2.1 IPR Example Application

This section demonstrates how to apply each IPR by using an example. Table 2.1 contains information that will be used for the prediction of the IPR.

Vogel's Method: In order to use Vogel's equation, one needs to have well test information including reservoir pressure and flowing bottomhole pressure and oil production rate. Using this information and rearranging Eq. 5, one can calculate the maximum flow rate. Using the flow rate of 134 BOPD, the maximum flow rate is:

$$q_{max} = \frac{134}{1 - 0.2 \left(\frac{1000}{1347} \right) - 0.8 \left(\frac{1000}{1347} \right)} = 126 \text{ BOPD}$$

After q_{max} is determined, Eq. 5 can be used to estimate production rates at other values of flowing wellbore pressure to develop an inflow performance curve. For example the flow rate at a 500 psi flowing bottomhole pressure would be

CHAPTER 2

Table 2.1 - Well Test Information Used for Example INFLOW PERFORMANCE RELATIONSHIPS

The various inflow performance relationships to be evaluated were presented in Chapter 1. This chapter discusses how the relationships are applied by using an example. In addition, a spreadsheet program developed to perform the comparison is described.

2.1 IPR Example Application

This section demonstrates how to apply each IPR by using an example. Table 2.1 contains information that will be used for the prediction of the IPR.

Vogel's Method: In order to use Vogel's equation, one needs to have well test information including reservoir pressure and flowing bottomhole pressure and oil production rate. Using this information and rearranging Eq. 5, one can calculate the maximum flow rate. Using the flow rate of 134 BOPD, the maximum flow rate is

$$q_{o,\max} = \frac{134}{1 - 0.2\left(\frac{1000}{1347}\right) - 0.8\left(\frac{1000}{1347}\right)^2} = 326 \text{ BOPD}$$

After $q_{o,\max}$ is determined, Eq. 5 can be used to estimate production rates at other values of flowing wellbore pressure to develop an inflow performance curve. For example the flow rate at a 500 psi flowing bottomhole pressure would be

Table 2.1 - Well Test Information Used for Example

Fetkovich's Method: For this method, one should have multirate test data of

at least three $p_r = 1347$ psi $p_b = 2020$ psi $S = 2$

available, then one can assume that the exponent n is unity and perform the calculation.

Using the multirate test data in Table 2.1, one would generate a table similar to the one

Test	q_o , BOPD	p_{wf} , psi
1	59	1200
2	97	1100
3	134	1000

q_o , BOPD	p_{wf} , psi	q_o^2/p_{wf}^2 , psi ⁻²
59	1200	274.4
97	1100	604.4
134	1000	814.4

The data in the above table is plotted on a log-log graph to determine the parameters of Fetkovich's relation n and C . Fig 2.1 presents this plot. The exponent n is the inverse of the slope of this graph and is 1.05 for this example.

After separating and isolating q_{max} from Eq. 7 and using the computed n value, the maximum flow rate can be obtained.

$$q_{max} = \frac{134}{\left[1 - \left(\frac{1000}{1347}\right)^{1.05}\right]^{1.05}} = 113 \text{ BOPD}$$

$$q_o = 360 \left(1 - 0.2 \left(\frac{500}{1347} \right) - 0.8 \left(\frac{500}{1347} \right)^2 \right) = 266 \text{ BPD}$$

Fetkovich's Method: For this method, one should have multirate test data of at least three points in order to calculate the exponent n and C . If the information is not available, then one can assume that the exponent n is unity and perform the calculation. Using the multirate test data in Table 2.1, one would generate a table similar to the one that follows so that a log-log plot can be made.

q_o , BOPD	p_{wf} , psi	$(p_r^2 - p_{wf}^2)10^3$, psi ²
59	1200	374.4
97	1100	604.4
134	1000	814.4

The data in the above table is plotted on a log-log graph to determine the parameters of Fetkovich's relation n and C . Fig 2.1 presents this plot. The exponent n is the inverse of the slope of this graph and is 1.05 for this example.

After separating and isolating $q_{o,max}$ from Eq. 7 and using the computed n value, the maximum flow rate can be obtained.

$$q_{o,max} = \frac{q_o}{\left[1 - \left(\frac{p_{wf}}{p_r} \right)^2 \right]^n}$$

$$q_{o,max} = \frac{134}{\left[1 - \left(\frac{1000}{1347} \right)^2 \right]^{1.05}} = 312 \text{ BOPD}$$

Finally, the estimated production rates at different flowing pressures can be evaluated from Eq. 7 and the construction of the IPR curve completed. For example, at a flowing bottomhole pressure of 300 psi

$$q_o = 293 \left[1 - \left(\frac{300}{1147} \right)^{1.0539} \right] = 257 \text{ BOPD}$$

It should be remarked that the value of C was not used in this calculation unless one prefers Eq. 6 for the computation of flow rates at different pressures.

Just as Blount and Glaze's method like the previous method, multipoint data is necessary to apply the method of Blount and Glaze. The parameters C and D are determined by plotting the pressure differential divided by the flow rate versus the flow rate. Using the test data, the following needed information and table is prepared.

Fig. 2.1 - Fetkovich's plot for the example calculation.

Fig. 2.1 is a plot of these values on logarithmic paper which allows the determination of the intercept, C, and the slope, D. These parameters are 2.41 psi/BOPD and 0.0013 psi/BOPD^{1.0539}, respectively.

Using these values and solving Eq. 9 for the maximum flow rate by letting the flowing bottomhole pressure equal zero yields

Finally, the estimated production rates at different flowing pressures can be evaluated from Eq. 7 and the construction of the IPR curve completed. For example, at a flowing bottomhole pressure of 500 psi

$$q_o = 292 \left[1 - \left(\frac{500}{1347} \right)^2 \right]^{1.05} = 267 \text{ BOPD}$$

It should be remarked that the value of C was not used in this calculation unless one prefers to use Eq. 6 for the computation of flow rates at different pressures.

Jones, Blount and Glaze's Method: Like the previous method, multipoint data is necessary to apply the method of Jones, Blount and Glaze. The parameters C and D are determined by plotting the pressure differential divided by the flow rate versus the flow rate. Using the test data, the following needed information and table is prepared.

q_o , BOPD	p_{wf} , psi	$(p_r - p_{wf})/q_o$, psi/BOPD
59	1200	2.49
97	1100	2.55
134	1000	2.59

Fig. 2.2 Jones, Blount and Glaze plot for the example calculation.

Fig. 2.2 is a plot of these values on cartesian paper which allows the determination of the intercept, C, and the slope, D. These parameters are 2.41 psi/BOPD and $0.0013 \text{ psi/BOPD}^2$, respectively.

Using these values and solving Eq. 9 for the maximum flow rate by letting the flowing bottomhole pressure equal zero yields

$$q_{\text{max}} = \frac{-C + \sqrt{C^2 + 4D(p_i - p_w)}}{2D}$$

$$q_{\text{max}} = \frac{-2.41 + \sqrt{2.41^2 + 4(0.0013)(1347 - 0)}}{2(0.0013)} = 449 \text{ BOPD}$$

Flow rates at other values of flowing pressure can be determined by using the above relation. At a flowing bottomhole pressure of 500 psi, the flow rate is estimated as

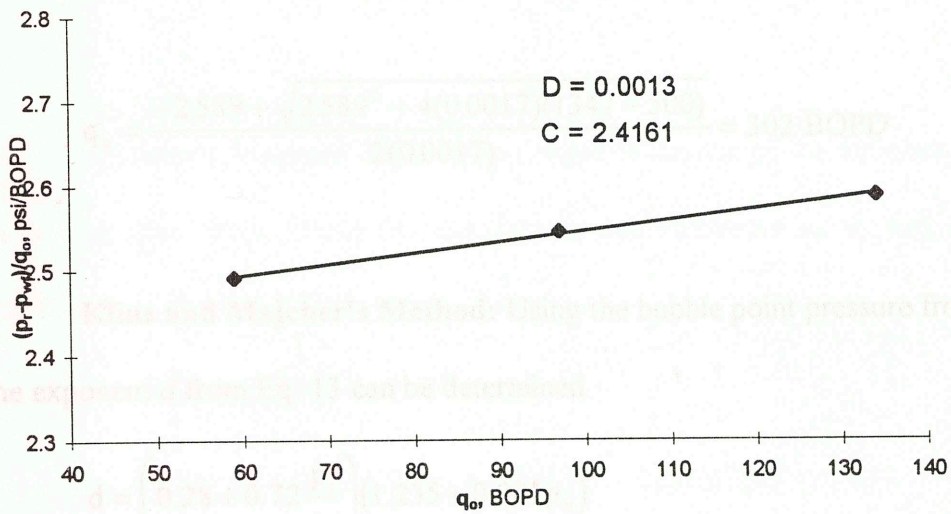

Fig. 2.2 - Jones, Blount and Glaze plot for the example calculation.

$$q_{o,max} = \frac{-C + \sqrt{C^2 + 4D(p_r - p_{wf})}}{2D} = 302 \text{ BOPD}$$

$$q_{o,max} = \frac{-2.41 + \sqrt{2.41^2 + 4(0.0013)(1347 - 0)}}{2(0.0013)} = 449 \text{ BOPD}$$

Flow rates at other values of flowing pressure can be determined by using the above relation. At a flowing bottomhole pressure of 500 psi, the flow rate is estimated as

$$q_o = \frac{-2.589 + \sqrt{2.589^2 + 4(0.0017)(1347 - 500)}}{2(0.0017)} = 302 \text{ BOPD}$$

Klins and Majcher's Method: Using the bubble point pressure from Table 2.1 the exponent d from Eq. 13 can be determined.

$$d = \left(0.28 + 0.72 \frac{p_r}{p_b} \right) (1.235 + 0.001 p_b)$$

$$d = \left(0.28 + 0.72 \frac{1347}{2020} \right) (1.235 + 0.001(2020)) = 2.478$$

By rearranging Eq. 12, the maximum flow rate can be obtained

$$q_{o,max} = \frac{q_o}{\left\{ 1 - 0.295 \left(\frac{p_{wf}}{p_r} \right) - 0.705 \left(\frac{p_{wf}}{p_r} \right)^d \right\}}$$

$$q_{o,max} = \frac{134}{\left\{ 1 - 0.295 \left(\frac{1000}{1347} \right) - 0.705 \left(\frac{1000}{1347} \right)^{2.478} \right\}} = 302 \text{ BOPD}$$

From this estimate of the maximum flow rate, the IPR will be plotted by calculating flow rates at desired flowing pressures from Eq. 12. If one takes a pressure value of 500 psi, then the resulting flow rate would be

$$q_{o,max} = 333 \left\{ 1.0 - 0.295 \left(\frac{500}{1347} \right) - 0.705 \left(\frac{500}{1347} \right)^{2.478} \right\} = 251 \text{ BOPD}$$

Sukarno's Method: This method requires the use of the estimated skin factor to predict flow rates. Using the skin factor, one calculates a_1 , a_2 and a_3 using the coefficients in Table 1.1. This yields

$$a_n = b_0 + b_1 S + b_2 S^2 + b_3 S^3$$

$$a_0 = 1.03940 + 0.12657(2) + 0.0135(2)^2 - 0.00062(2)^3 = 1.342$$

$$a_1 = 0.01668 - 0.00385(2) + 0.00217(2)^2 - 0.0001(2)^3 = 0.017$$

$$a_2 = -0.0858 + 0.00201(2) - 0.00456(2)^2 + 0.0002(2)^3 = -0.098$$

$$a_3 = 0.00952 - 0.00391(2) + 0.0019(2)^2 - 0.00001(2)^3 = 0.009$$

Next the FE value is calculated from Eq. 15 to yield

$$FE = \left\{ a_0 + a_1 \left(\frac{p_{wf}}{p_r} \right) + a_2 \left(\frac{p_{wf}}{p_r} \right)^2 + a_3 \left(\frac{p_{wf}}{p_r} \right)^3 \right\}$$

$$FE = \left\{ 1.342 + 0.017 \left(\frac{1000}{1347} \right) - 0.098 \left(\frac{1000}{1347} \right)^2 + 0.009 \left(\frac{1000}{1347} \right)^3 \right\} = 1.3$$

The maximum flow rate is then determined by using Eq. 14

$$q_{o,max@S=0} = \frac{q_o}{FE \left\{ 1 - 0.1489 \left(\frac{p_{wf}}{p_r} \right) - 0.4418 \left(\frac{p_{wf}}{p_r} \right)^2 - 0.4093 \left(\frac{p_{wf}}{p_r} \right)^3 \right\}}$$

$$q_{o,max@S=0} = \frac{134}{1.3 \left\{ 1 - 0.1489 \left(\frac{1000}{1347} \right) - 0.4418 \left(\frac{1000}{1347} \right)^2 - 0.4093 \left(\frac{1000}{1347} \right)^3 \right\}} = 215 \text{ BOPD}$$

The flow rate at a given value of flowing bottomhole pressure is obtained by computing a new FE value and then using Eq. 14. From this calculation at different flowing pressures, an IPR curve can be constructed. At a value of 500 psi,

$$FE = \left\{ 1.342 + 0.017 \left(\frac{500}{1347} \right) - 0.098 \left(\frac{500}{1347} \right)^2 + 0.009 \left(\frac{500}{1347} \right)^3 \right\} = 1.34$$

$$q_{o,actual} = 215 \times 1.34 \left\{ 1 - 0.1489 \left(\frac{500}{1347} \right) - 0.4418 \left(\frac{500}{1347} \right)^2 - 0.4093 \left(\frac{500}{1347} \right)^3 \right\} = 248 \text{ BOPD}$$

These example calculations are summarized in Table 2.2. As indicated, the calculated values vary among the methods.

Table 2.2 - Summary of the Calculated Flow Rates for the Example

2.2 Methodology

To analyze the data used in this study, a spreadsheet program was created to perform the rate-pressure calculations for each IPR method. Fig. 2.3 is an illustration of the calculation sheet of this program. Input parameters include the test data point (rates and pressures), average reservoir pressure, and bubble point pressure. Additional information required for each method are included in the parameters section. These include the exponents for the multirate methods and the skin factor for Sukarno's method. In the lower half, actual multipoint test data are imported for comparison purposes. Finally, a column was allocated for each method to estimate the flow rate at a given pressure. These values are calculated from the test data for the actual flowing bottomhole pressure. This allows a direct comparison between the actual flow rate and the calculated one.

This program was used to analyze the field data collected for this study. The petroleum literature was searched for suitable multirate tests. In total 26 multirate tests were collected from 12 fields for analysis. Four fields are from Oklahoma while eight are foreign fields. Test data range from the 1930's to the 1990's and cover a variety of reservoir conditions.

Fields and data were chosen in such a way that problems due to transient effects were avoided. Generally the tests consisted of flow-after-flow or isochronal tests of a few hours duration. The testing sequence varied from well to well. A total number of 125 test points have been analyzed. The pressure drawdown in these wells ranged from 2% to 90% with the majority being below 60%, based on the reservoir pressure. The

calculated pressure-rate information was then compared to the field data both in a graphical and tabular format. This provided a means to make a qualitative comparison of the various IPR methods. In addition, percent differences were calculated for each data point and averaged on a well-by-well basis for quantitative comparisons.

In this chapter, the IPR methods are compared using field data. Well test data for 26 cases were collected from the petroleum engineering literature. Each data set was analyzed with three cases presented in this chapter. The remainder analyses are presented in Appendix A. Table 3.1 identifies the cases used in this study by a well identifier and the reference for the data.

3.1. Case 1

In 1951, Matthews and Howell¹ presented qualitative test data for a well producing from the Turner zone in the Cary City Field of Oklahoma. The test was made over a period of 100 days and well rate data taken in a random manner rather than in an increasing or decreasing order. The average reservoir pressure was 1040 psi with an estimated initial well pressure of 600 psi. A skin value of zero was assumed. The field data are presented in Table 3.2.

Table 3.2 also shows being the test information at a flowing bottomhole pressure of 600 psi, representing a 42% pressure drawdown. As can be seen, the absolute open flow potential (AOF) varies from 2432 to 3704 BOPD. The largest flow rate was obtained using Vogel's IPR while the smallest rate was obtained using Fetkovich's method.

Fig. 3.1 presents the IPR curves for the methods used. Visual inspection of the graph indicates that the methods of Fetkovich and Jones, Doolal and Glaze do a very

CHAPTER 3

IPR COMPARISONS

In this chapter, the IPR methods are compared using field data. Well test data for 26 cases were collected from the petroleum engineering literature. Each data set was analyzed with nine cases presented in this chapter. The remainder analyses are presented in Appendix A. Table 3.1 identifies the cases used in this study by a well identifier and the source of the data.

3.1. Case 1

In 1931, Millikan and Sidewell¹⁵ presented multirate test data for a well producing from the Hunton Lime in the Carry City Field of Oklahoma. The test was made over a period of about two weeks and rate data taken in a random manner rather than in an increasing or decreasing order. The average reservoir pressure was 1600 psi with an estimated bubble point pressure of 2530 psi. A skin value of zero was assumed. The field data are presented in Table 3.2.

Table 3.3 was created using the test information at a flowing bottomhole pressure of 1267 psi, representing a 21% pressure drawdown. As can be seen, the absolute open flow potential (AOF) varies from 2652 to 3706 BOPD. The largest flow rate was calculated with Vogel's IPR while the smallest rate was obtained using Fetkovich's method.

Fig. 3.1 presents the IPR curves for the methods used. Visual inspection of the graph indicates that the methods of Fetkovich and Jones, Blount and Glaze do a very

good job of estimating the actual well performance. The other methods capture the general shape of the data but overestimate the performance. If a straight-line assumption was used in this case, a maximum flow rate of 6054 BOPD would have been calculated from the test point. This estimate is over 60% greater than the highest predicted rate by the IPFR methods. This shows the importance of using a multiphase

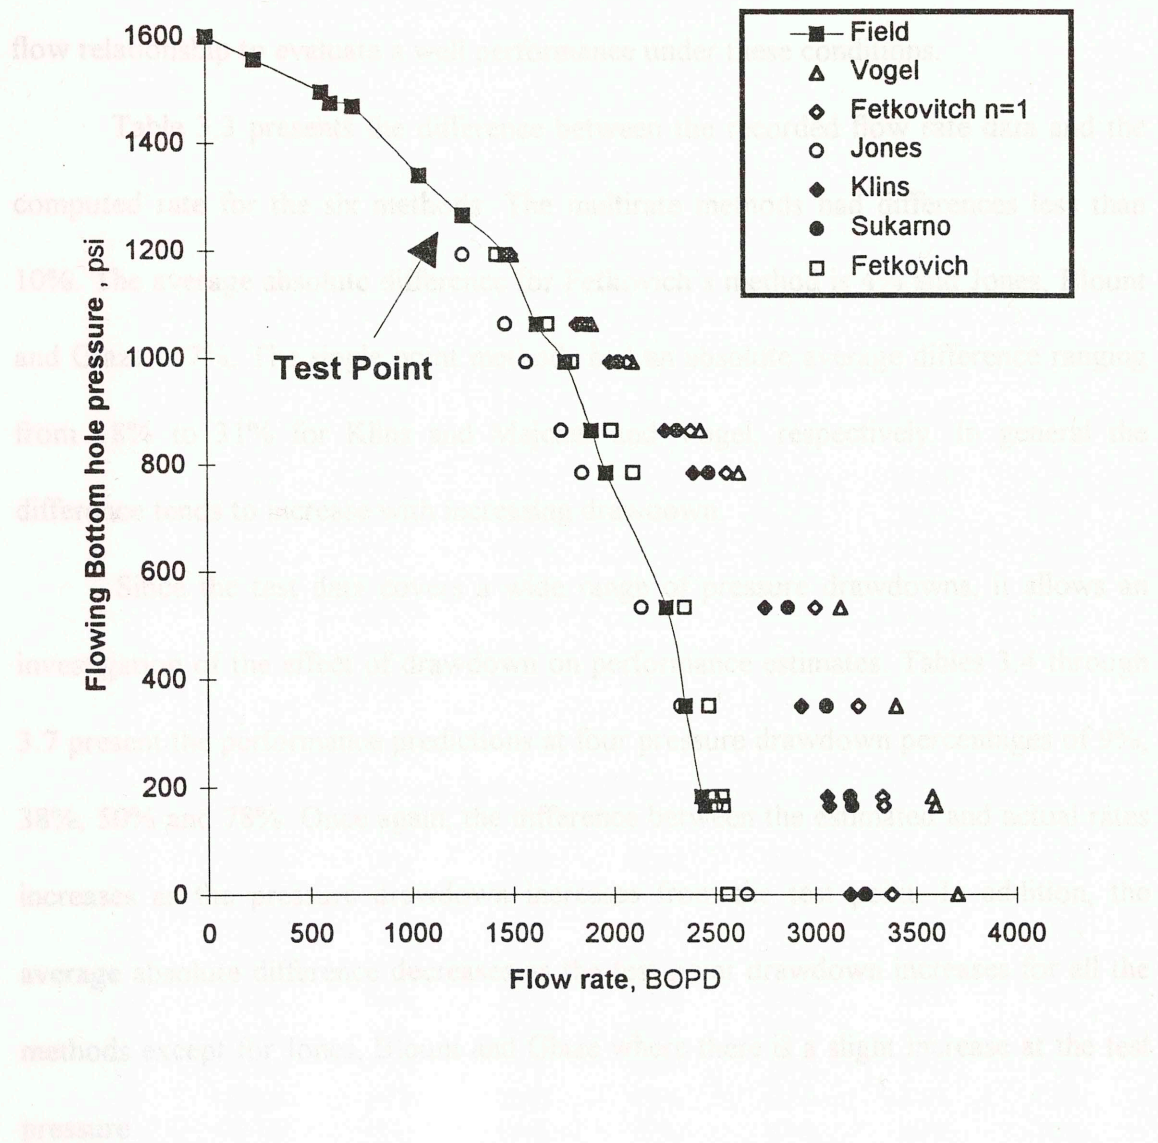

Fig. 3.1 - Performance curves for the Carry City Well.

good job of estimating the actual well performance. The other methods capture the general shape of the data but overestimate the performance. If a straight-line assumption was used in this case, a maximum flow rate of 6054 BOPD would have been calculated from the test point. This estimate is over 60% greater than the highest predicted rate by the IPR methods. This shows the importance of using a multiphase flow relationship to evaluate a well performance under these conditions.

Table 3.3 presents the difference between the recorded flow rate data and the computed rate for the six methods. The multirate methods had differences less than 10%. The average absolute difference for Fetkovich's method is 4% and Jones, Blount and Glaze is 7%. The single point methods had an absolute average difference ranging from 18% to 31% for Klins and Majcher and Vogel, respectively. In general the difference tends to increase with increasing drawdown.

Since the test data covers a wide range of pressure drawdowns, it allows an investigation of the effect of drawdown on performance estimates. Tables 3.4 through 3.7 present the performance predictions at four pressure drawdown percentages of 9%, 38%, 50% and 78%. Once again, the difference between the estimated and actual rates increases as the pressure drawdown increases from the test point. In addition, the average absolute difference decreases as the test point drawdown increases for all the methods except for Jones, Blount and Glaze where there is a slight increase at the test pressure.

For example, if one takes Vogel's method, the AOF diminishes from 5108 BOPD at 9% drawdown to 2564 BOPD at 78%. This is almost a 100% reduction in the estimate. The average difference decreases from 72% at a flowing pressure of 1470

Average Difference :		1.7%	0.2%	1.1%	7.9%	0.7%	0.2%

3.2 Cases 2 and 3

The second well¹⁸ presented is from the Keokuk Pool in Senoole County, Oklahoma. Two sets of data were obtained, the first was run in December 1934 and the second in August 1935. These data were selected to evaluate the effect of depletion on the IPR methods. During this period, the reservoir pressure dropped from 1734 psi to

psi to almost 1.7% with a test pressure of 351 psi. The other single point methods are comparable to Vogel's with less severity.

On the contrary for this case, except for the lowest pressure drawdown, Fetkovich's method is invariable throughout the analysis with an average difference varying from 4% to 1.1%. For this particular case, a 19% pressure drawdown was sufficient to predict the performance of the well using Fetkovich's method. With Jones, Blount and Glaze, the results were not the same due to the change of the constants C and D which govern the method. This had the consequence of varying the average difference and AOF. The best or the smallest average absolute difference was obtained at a 50% drawdown rather than at the largest one of 78%. This can be illustrated by the fact that the data points did not lie on a perfect line as shown in Fig. 3.2. The test point used affects the values of C and D and the estimated performance.

In summary, Fetkovich's relation provided the best estimates of well performance over the entire range of interest. In general, the difference in performance predictions increased as the pressure drawdown increased from the test pressure. Also, the average difference in the predictions decreased as the test pressure drawdown increased.

3.2 Cases 2 and 3

The second well¹⁶ presented is from the Keokuk Pool in Seminole County, Oklahoma. Two sets of data were obtained, the first was run in December 1934 and the second in August 1935. These data were selected to evaluate the effect of depletion on the IPR methods. During this period, the reservoir pressure dropped from 1734 psi to

Fig. 3.2 - Jones, Blount and Glaze plot with all the test data for the Carry City Well.

1609 psi. For this analysis, the bubble point pressure was estimated at 3420 psi. The test data are shown in Table 3.8. The test data only covers approximately 40% of the pressure range.

Tables 3.9 and 3.10 present the calculated flow rates for the different methods estimated from test data at pressure drawdowns of 13% and 12%. Figs. 3.3 and 3.4 present the results graphically. Once again, all the methods provide a range of rate predictions with the difference decreasing with increasing pressure drawdown. For the first test, the maximum flow rates were evenly spaced between the various methods. In addition, there was not a large demarcation between the single point methods and the multipoint methods. But six months later, having similar test point information with almost identical drawdowns, one can differentiate two groups of curves represented by the single point methods and the multipoint methods.

Tables 3.9 and 3.10 show the difference in predicted and observed rates. In the first case, the methods of Fetkovich, Jones, Blount and Glaze, and Klins and Majcher all yield predicted differences less than 10% with average absolute differences around 6%. As a matter of fact, both Klins and Majcher and Jones, Blount and Glaze give almost the same AOF. However, at the second pressure level, the difference in the predictions of Klins and Majcher increase above 10%.

It is also interesting to note that there is little change in the estimate of the AOF for the single point methods in this case while the multipoint methods yielded approximately a 20% reduction in the predicted maximum rate. This effect results from the utilization of more than one data point in the multipoint methods which should improve their reliability. Table 3.11 presents the change in AOF after six month for

each method. The change in the multipoint methods is due to the changes in the n , C , and D values presented in Figs. 3.5 and 3.6. This observation is important when one

wants to forecast future performance since the flow coefficients change with depletion and may affect future estimates. One also notes the AOF predicted by Klins and Majcher increased between the two test periods.

Vogel	Fetkovitch	Fetkovitch	Jones	Klins	Sukarno
3%	3%	23%	22%	4%	4%

This example tends to indicate that the reliability of the various performance methods may change during the life of a well. In addition, the multipoint methods appear to yield the most reliable predictions.

3.3 Cases 7 and 10

In this section, two wells, where the deliverability exponent n from Fetkovitch's equation is greater than one are analyzed. These wells produced from the Lucien Pool, Noble County, Oklahoma and the South Burbank Pool, Osage County, Oklahoma. Table 3.12 presents the test data for each well. Well D, located in Noble County, had a reservoir pressure of 1800 psi and an estimated bubble point pressure of 3640 psi while Well G in Osage County had a reservoir pressure of 266 psi and an estimated bubble point pressure of 2965 psi. For both wells, a skin factor of zero was assumed. The minimum and maximum drawdown for the first Well D was 6.3% and 36%, respectively. The maximum pressure drawdown for Well G was greater than 50%.

Figs. 3.7 and 3.8 show the predicted performance for each well. It appears Fetkovitch's method is most reliable in estimating the data. In this case, Fetkovitch's method provided the largest estimate of AOF compared to the other methods and also

each method. The change in the multipoint methods is due to the changes in the n , C , and D values presented in Figs. 3.5 and 3.6. This observation is important when one wants to forecast future performance since the flow coefficients change with depletion and may affect future estimates. One also notes the AOF predicted by Klins and Majcher increased between the two test periods.

This example tends to indicate that the reliability of the various performance methods may change during the life of a well. In addition, the multipoint methods appear to yield the most reliable predictions.

3.3 Cases 7 and 10

In this section, two wells¹⁶ where the deliverability exponent n from Fetkovich's equation is greater than one are analyzed. These wells produced from the Lucien Pool, Noble County, Oklahoma and the South Burbank Pool, Osage County, Oklahoma. Table 3.12 presents the test data for each well. Well D, located in Noble County, had a reservoir pressure of 1800 psi and an estimated bubble point pressure of 3640 psi while Well G in Osage County had a reservoir pressure of 866 psi and an estimated bubble point pressure of 2985 psi. For both wells, a skin factor of zero was assumed. The minimum and maximum drawdown for the first Well D was 6.5% and 38%, respectively. The maximum pressure drawdown for Well G was greater than 50%.

Figs. 3.7 and 3.8 show the predicted performance for each well. It appears Fetkovich's method is most reliable in estimating the data. In this case, Fetkovich's method provided the highest estimate of AOF compared to the other methods and also

		461	450
		420	539

Fig. 3.8 - Performance curves for Well G, South Burbank Pool, Osage County, OK.

estimated the high flow rates better. For Well G, the method predicts a substantially higher AOF of 747 BOPD versus 421 to 534 BOPD for the other methods. Tables 3.13 and 3.14 present the calculated values.

These tables also reflect the difference between the calculated and observed values. For Well D, Fetkovich tends to underpredict the observed values, while overpredicting in the case of Well G. In both cases, the average absolute difference in the predictions were less than 10%. The other methods yielded average absolute differences greater than 15%.

In both cases, Vogel's method appears to be more reliable than the other methods with the exception of Fetkovich which is the first time this has occurred. In addition, Jones, Blount and Glaze provided estimates that are substantially different from the multipoint method of Fetkovich which was surprising in view of the earlier comparisons.

From this comparison, it has been shown the multipoint methods do not always provide the most reliable predictions. However, Fetkovich's multipoint method did provide the best estimates in this case.

3.4 Cases 13 and 15

Fetkovich⁶ presented flow-after-flow data for 14 wells producing from solution-gas drive carbonate reservoirs in Field A. Table 3.15 provides reservoir properties while Table 3.16 presents test data for Wells 3 and 14. The main purpose for this example is to demonstrate that the various methods may produce different results for wells producing from similar reservoirs and geological environments.

Tables 3.17 and 3.18 present the calculated results for Wells 3 and 14 predicted from pressure drawdown data of 29% and 38%, respectively. The calculation of parameters for the multirate methods are based on three data points. As can be seen from Figs. 3.9 and 3.10 all the predictions are relatively close for each method.

For Well 3, Fetkovich's method stands apart from the other methods. It predicts the two measured data points very well, as does Jones, Blount and Glaze. However, it provides a lower estimate of the AOF than the other methods. This is in contrast to Well 14 where all the methods predict the measured data points equally well and all yield similar AOFs. In addition, Fetkovich's method no longer has the lowest AOF prediction. Indeed, the order of the methods have changed from lowest to highest. This indicates the uncertainty of using one method over another even for wells in similar producing environments.

3.5 Cases 14 and 24

The next two wells analyzed were also presented by Fetkovich⁶. These wells were high rate, medium pressured wells producing from 9000 ft. The wells test data are presented in Table 3.19.

These wells had a limited maximum drawdown of approximately 20%, which limited the comparison over the entire pressure range. Both wells were analyzed at a pressure drawdown of 13%. As Figs. 3.11 and 3.12 and Tables 3.20 and 3.21 illustrate, there is a huge difference between the AOFs estimated by the different methods. However, all the methods estimated the measured data reasonably well. This resulted from the limited extrapolation from the test points.

An interesting point appeared in this example. The single point method of Klins and Majcher yielded results similar to the multipoint methods and substantially different from Vogel's or Sukarno's methods. Evidently their bubble point correction has some influence at higher pressures near the bubble point, a condition they considered in developing their IPR.

3.6 Overall comparison

The preceding sections have presented a variety of comparisons for wells producing under different conditions. In total, 26 different cases have been examined with 8 presented in this chapter. The remaining 18 are shown in Appendix A.

Table 3.22 presents a summary of the average absolute difference for each method for all the wells examined. As indicated in this table, not one method always provided the most reliable estimates of the actual well data analyzed. However, some general comments can be made based on this table and the cases presented in this study.

The multipoint methods tends to do a better job of predicting performance than the single point methods. As a matter of fact, the total average absolute difference is almost twice as great for the single point methods in comparison to Fetkovich's multipoint method, 15% compared to 8%. Overall, the single point method of Vogel, Fetkovich, and Sukarno provided similar average differences in the cases examined while Klins and Majcher was only slightly better.

Table 3.23 presents a ranking of the IPR methods. This rank is only based on the arithmetic average of the absolute difference for the 26 tests analyzed in this study.

Table 3.22 - Comparison of the Absolute Difference for Each Method

Table 3.23 - Ranking of the IPR Methods Based on this Study

Method	Rank
Fetkovich (multipoint)	1
Jones, Blount and Glaze	2
Klins and Majcher	3
Sukarno, Vogel, Fetkovich (single point)	4

The primary concern in this study was to evaluate the reliability of the IPR methods based on actual production test data. Detailed analysis and comparisons for five different cases were presented in Chapter 2 while additional cases were presented in Appendix A. From this study the following conclusions are presented:

1. There is no one method which is the most suitable for every test. It has been observed that in one case method A will provide the most reliable estimates while providing the worst estimates in the next case. From this observation, consideration should be given for using more than one method in predicting performance in order to provide a range of possible outcomes.

2. Overall, Fetkovich's multipoint method tended to be the most reliable. It has been shown based on all the test data of this study that the overall absolute difference for Fetkovich's method was less than the other. Also, Fetkovich's method provided

CONCLUSIONS AND RECOMMENDATIONS

In this study, five different methods to predict the pressure-production performance of oil wells producing from solution-gas drive reservoirs have been presented. These are the methods of Vogel, Fetkovich, Jones, Blount and Glaze, Klins and Majcher, and finally Sukarno methods. Each of them require parameters that are normally available from a production test. The methods can be separated into multipoint methods and single point methods.

The primary concern in this study was to evaluate the reliability of the IPR methods based on actual production test data. Detailed analysis and comparisons for five different cases were presented in Chapter 3 while additional cases were presented in Appendix A. From this study the following conclusions are presented.

1. There is no one method which is the most suitable for every test. It has been observed that in one case method A will provide the most reliable estimates while providing the worst estimates in the next case. From this observation, consideration should be given for using more than one method in predicting performance in order to provide a range of possible outcomes.

2. Overall, Fetkovich 's multipoint method tended to be the most reliable. It has been shown based on all the test data of this study that the overall absolute difference for Fetkovich's method was less than the other. Also, Fetkovich's method provided

steady performance predictions throughout the pressure drawdown range while the single point methods appeared to be more sensitive to the drawdown pressure of the test point.

3. Due to the effects of depletion, one IPR method may be more reliable at one reservoir pressure but not at the second pressure. This may be caused by changes in reservoir with time which can lead to changes in its flow properties.

NOMENCLATURE

- k = permeability, md
- A = variable in Uhri and Blount method, BOPD/psi
- A' = variable in Kelkar and Cox method, BOPD/psi³
- B' = variable in Kelkar and Cox method, BOPD/psi
- C = Fetkovich's coefficient, BOPD/(psi)²ⁿ
- C = Jones *et al.*'s laminar flow coefficient, psi/BOPD
- D = Jones *et al.*'s turbulence flow coefficient, psi/BOPD²
- d = Klins and Majcher flow exponent
- J* = Standing's modified productivity index, BOPD/psi
- J* = Kelkar and Cox's modified productivity index, BOPD/psi
- n = Fetkovich's flow exponent
- n = variable in Uhri and Blount method, psi
- p_b = bubble point pressure, psi
- p_{wf} = flowing bottomhole pressure, psi
- p_r = average reservoir pressure, psi
- q_o = oil production rate, BOPD
- q_{o max} = maximum oil production rate, BOPD
- r_e = external drainage radius, ft
- r_w = well radius, ft
- h = producing formation thickness, ft
- S = skin effect excluding turbulence effects
- ρ = density, lb_m/cu.ft
